FOREWORD

This report was prepared by the Standard Oil Development Company, under USAF Contract No. AF 33(038)-14593. The contract was initiated under Research and Development Order No. 613-15, "Hydraulic Fluids and Lubricants MX 1576", and was administered under the direction of the Materials Laboratory, Directorate of Research, Wright Air Development Center, with Capt L. D. Christensen and Lt J. A. King acting as project engineers. This is the final report on this work, and it presents all the information obtained during the contract period, July 8, 1950 - August 7, 1952.

ABSTRACT

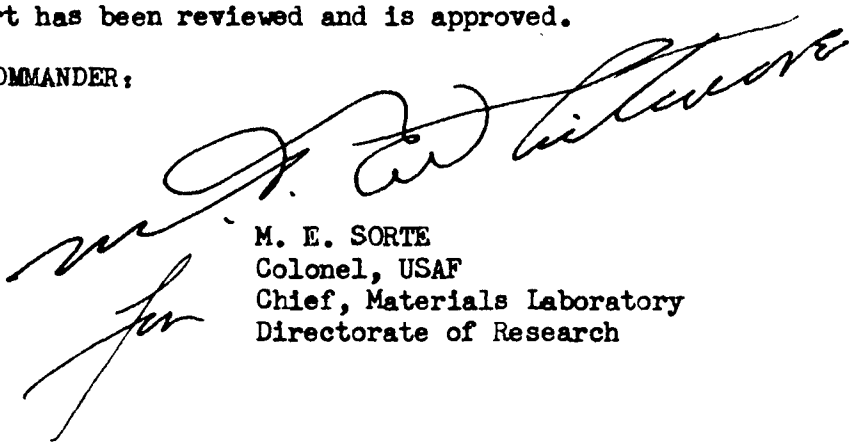

This report is a compilation of all the information obtained under Contract No. AF 33(038)-14593, concerned with means of increasing the availability of synthetic lubricants for use at low and high temperatures.

The diesters of straight-chain dibasic acids lead the field of esters suitable as lubricants for use at both low and high temperatures, because of their desirable combinations of properties and potentially good availability. Adipic, azelaic, and sebacic acids are the most readily available dibasic acids suitable for ester lubricant production, while the petroleum derived Oxo alcohols appear to be the most available alcohols for this application. In addition, however, certain diesters of polypropylene glycols appear equivalent to dibasic acid esters in all the characteristics studied so far, and this type of ester therefore represents a promising source of synthetic oil. Mono-esters may be satisfactory lubricants where high temperatures are not encountered. The presence of small quantities of impurities are believed to cause variations in the oxidation and thermal stability of esters. The SAE E.P. Lubricants Tester is capable of measuring the load-carrying ability of synthetic lubricants, but further work is required to develop a completely reliable test for predicting full-scale gear performance.

PUBLICATION REVIEW

This report has been reviewed and is approved.

I - INTRODUCTION

The work done under this contract has been defined in a general way as a study of means for increasing the availability of ester-type synthetic lubricants suitable for aircraft application. This study has been approached in two ways: (1) A survey of the potential availability of raw materials; and (2) evaluation of many types of esters in an effort to find a wider selection of suitable products from which finished oils could be developed. It is believed that the most worthwhile contribution of this work has been obtained from the second approach, which has resulted in the cataloguing of some critical properties of a wide variety of esters. This project involved, first, an extensive survey of data already available in the literature and some unpublished reports, and, second, expansion of these data by evaluation of more critical properties for known types of esters. All of the information obtained during the two years' work is compiled in the Appendix to this report. Appendix I covering the literature survey, Appendix II, the results of the additional work, and Appendix III, IV, & V giving the more important conclusions reached during these studies.

In this report the salient points and important conclusions revealed by each phase of the work carried out will be mentioned and referred to in the appropriate appendix. For a detailed discussion of the data the reader will be referred to the proper appendix. The reader will also be referred to the Appendix tables of this report for the complete data on a given phase of work or type of ester.

II - RAW MATERIALS AVAILABILITY

An attempt was made to estimate the potential availabilities of some of the more prominent ester raw materials. However, it was quickly apparent that it was impossible in certain cases for a private company to make reliable estimates, since proprietary information was involved. The best availability figures possible, without access to the actual production capacities, were presented in the AF Technical Report No. 6663. It was understood that the Aircraft Production Resources Division was making a more complete and reliable survey.

Some generalizations on availability are possible without actual production statistics. Of the chain-type dibasic acids suitable for ester lubricant manufacture, sebacic, azelaic, and adipic acids lead the field from the standpoint of availability. Potentially the most available of these is adipic acid because it can be derived from petroleum. For the same reason the Oxo alcohols have the best potential availability among the alcohols suitable for ester lubricants. Alcohols such as 2-ethylhexanol are also usually regarded as suitable for this application. However, it is possible that the starting raw materials for producing this alcohol (ethanol or acetylene) may have other strategic uses in time of emergency, and it is not certain that 2-ethylhexanol can be counted on for ester production. Glycols produced from ethylene oxide or propylene oxide will probably be available in reasonable quantities, although once again, ethylene and propylene may be required in other critical applications.

III - LITERATURE SURVEY

In Appendix I to this report, data have been compiled from various literature sources for over 800 compounds (mostly esters) of possible interest as synthetic lubricants. Appendix I Table 1 presents the bibliography for this report, and a number is assigned to each literature data source. The appropriate reference numbers are then found in the first column of the succeeding tables of data in Appendix I. Following is a list of the types of compounds for which the literature data may be found in the designated tables:

<u>Compound Type</u>	<u>Appendix Table Number</u>
Adipates	2, 3, 4
Substituted Adipates	5
Sebacates	6, 7
Azelates and Pimelates	8, 9
Esters of Other Dibasic Acids	10, 11

Glycol Center (with ether oxygens)	32
From Hydroxy-Acids	33, 34
Three Ester Groups Per Molecule	35

Along with providing a useful compendium of available information on ester-type lubricants, the literature survey furnished the necessary background for the further studies required. It was concluded from

this survey that esters, in general, had very desirable combinations of properties and warranted the serious consideration they have received as synthetic lubricants. It was also apparent that ester lubricants of nearly any desired viscosity could be made from widely available or potentially available raw materials. However, a considerable amount of further work appeared necessary to determine if esters were satisfactory as lubricants from all critical standpoints and if there were preferred types of esters among those of wide availability. To answer these and related questions, it was evident that the data available in the literature required expansion to include volatility, low temperature, stability, and lubrication properties of promising materials. Efforts were therefore turned toward the ester evaluation phase of the project.

IV - ESTER EVALUATION

All of the evaluation results obtained during the two years under the contract are presented in detail in Appendix II. For this work it was necessary to synthesize some esters in the laboratory to supplement those procured from commercial suppliers. These materials, designated in the tables as "laboratory preparations" were for the most part specific members of homologous series already known in the art. A search for new types of esters was not an object of this project.

A. Synthesis

The techniques used in preparing esters in the laboratory were thoroughly discussed in the AF Technical Report No. 6663. In general, the products were synthesized in the conventional manner employing commercial grade reactants. Either p-toluene sulfonic acid monohydrate or sodium hydrogen sulfate (usually 0.3 to 0.5% based on the ester) was used as catalyst. The effect of the catalyst on esterification rate is depicted in Figures 1 & 2 of Appendix II. The esters prepared in the laboratory were generally refined by vacuum distillation to produce a wide heart-cut for evaluation. The most effective acidity reduction method, employed after distillation, was adsorption on animal charcoal. High quality esters were prepared in this fashion.

B. Properties Desired in Synthetic Lubricants

The ever widening temperature range over which a lubricant must perform all of its functions has led to a steady increase in the use of synthetic oils. In many kinds of aviation equipment, and particularly in high-power gas turbine aircraft engines, synthetic lubricants are replacing inadequate mineral oils. Each piece of equipment may require some specific properties in the lubricant, but nearly all applications there are some fundamental lubricant properties which are important. In general, it is these fundamental properties which have been evaluated for the variety of esters studied in this project. These desired characteristics include:

1. Good viscosity-temperature relationship
2. Good viscosity-volatility relationship
3. Low melting and pour points
4. Stability toward oxidation, hydrolysis, and heat
5. Good lubrication characteristics

The following sections of the report designate in what Appendix tables and figures the data relating to these properties may be found. Pertinent conclusions arising from this work are discussed in Section V.

C. Viscosity-Temperature Characteristics and General Properties

The kinematic viscosities from 210° to -65°F of all lubricant materials either procured from commercial suppliers or synthesized in the laboratory are presented in Appendix II Tables 36 through 60. Viscosity-temperature relationships are expressed by three systems: ASTM Slope, V.I., and Hardimann and Nessen V.I.* Other general properties, including neutralization numbers, flash, fire, pour, and melting points, are also shown in these tables. Although flash points, and in some cases, vapor pressures, are presented, the subject of volatility is more adequately covered in succeeding tables. The effects of ester structure on viscosity-temperature characteristics are discussed thoroughly in the AF Technical Report No. 6663 and in Appendix IV.

The properties obtained for esters of mono-, di-, and tri-basic acids are given in Tables 36, 37, and 38. Polyhydric alcohol esters are covered in Tables 39 and 40, and some miscellaneous synthetic lubricant materials are given in Table 41. The low temperature viscosities for a series of adipates, azelates, and sebacates are depicted graphically in Appendix II Figure 3, and some other important low temperature properties for a variety of esters are shown in Table 42.

D. Viscosity-Volatility Characteristics

There are three common ways of measuring volatility: by determining vapor pressure, flash point, or evaporation rate. All three have been studied and employed to some extent in this program. The vapor pressure apparatus and procedure used are described in detail in Appendix III. It is a boiling point method which included distilling off an initial portion of the sample to avoid errors due to volatile contaminants. The evaporation apparatus and technique are described in Appendix IV.

The vapor pressure-temperature relationships for the esters on which vapor pressures were obtained are shown graphically in Appendix II Figures 4 through 12. The experimental points are plotted as log vp vs. $1/(t+230)$, with t being °C. In most cases the experimental data would conform just as well to lines representing log vp vs. $1/(t+273)$. However, the constant 230, as proposed by Cox,** should provide a better fit for the data over a larger portion of the liquid range and allow more accurate extrapolation. Vapor pressure-temperature data, taken from these figures, are also presented in Tables 43 and 44, along with viscosity

* Described in AF Technical Report No. 6663

** Cox, Ind. Eng. Chem., 28, 613 (1936)

data for the same materials. The boiling point of each compound at 2 mm. pressure is one measure of its volatility. The temperature at which each compound has thickened to 10,000 cs. (obtained from ASTM viscosity-temperature plots) is presented in Tables 43 and 44 as one measure of that compound's low temperature viscosity. The difference between these two temperatures is then an indication of the viscosity-volatility properties of the material, and may have some practical significance as an indication of the acceptable operating temperature range possible with the lubricant. This temperature difference, or Viscosity-Volatility Index as it might be termed, depends considerably on viscosity level, as would be expected. Therefore, comparisons of various compound types should be made at common levels of viscosity. The Viscosity-Volatility Indices are also tabulated in Tables 43 and 44. The significance and shortcomings of the Viscosity-Volatility Index are described in detail in Appendix III.

Flash point is a much simpler determination than vapor pressure. However, flash point is likely to reflect the presence of a small quantity of volatile contaminant rather than the volatility of the synthetic lubricant itself. Therefore, the correlation of flash point with vapor pressure gives some badly scattered points, as shown in Appendix II Figure 13. This correlation is improved, as shown, if two lines are drawn - one for carefully distilled esters (volatile contaminants removed), and one for esters which do not get this careful refinement.

Evaporation rate is probably a more realistic measure of lubricant volatility than either vapor pressure or flash point. The evaporation data obtained for a number of lubricants are presented in Figure 14. The amount of material evaporated (wt. % after 1 hr. at 392°F.) was found to correlate rather well with the vapor pressure of the lubricant (mm. at 400°F.), as shown in Figure 15.

E. Stability

1. Oxidation Stability

In order to study the oxidation stability of a variety of esters, it was necessary first to select an effective inhibitor which could be used in these esters, in common, and thus allow direct comparisons. Consideration was devoted toward screening a number of inhibitors for this purpose. These inhibitors, in di-2-ethylhexyl sebacate, were first evaluated in the Oxidation/Corrosion Stability Test at 250°F. (MIL-O-6081) and in an oxygen absorption rate test at 392°F. Results are presented in Appendix II Tables 45, 46, and 47. Promising inhibitors were next examined in a modification of the MIL-L-6387 Oxidation/Corrosion Stability Test at 347°F. The results, shown in Table 48, indicated phenothiazine to be superior

to the other inhibitors evaluated. Because of this performance, and the fact that phenothiazine was finding expanding application in the synthetic lubricant field, it was selected as the inhibitor for the ester evaluation work.

The oxidation stability of esters (inhibited with phenothiazine) was found to be affected to a large extent by apparently small quantities of impurities in the esters. This fact complicated the stability work and made reliable comparisons difficult. The data obtained on the stability of esters to oxidation are shown in Table 49. These data are discussed in Appendix IV.

2. Hydrolytic Stability

A limited number of esters were examined in the MIL-I-6387 Hydrolytic Stability Test. Results are presented in Table 50, and are discussed in AF Technical Report 6663.

3. Thermal Stability

A simple test was used to study thermal stability. The ester was maintained at 392°F for 48 hours under nitrogen, and decomposition was calculated from the change in acidity. A large number of esters were investigated in this test and the data are tabulated in Tables 51 and 52. When it became known that temperatures above 392°F were being attained in some aircraft equipment, some similar thermal stability tests were run at 455°F. The results are presented in Table 53. Thermal stability is discussed thoroughly in Appendix IV.

F. Lubrication Characteristics

Nearly all simple, uncompounded esters are similar in lubrication characteristics. Good load-carrying and anti-wear properties therefore require proper compounding. However, development of finished lubricants with good load-carrying ability is hampered by the lack of reliable laboratory test methods, which could be used for initial exploratory work. The last few months of this project were devoted to a study of laboratory test machines, primarily the SAE E.P. Lubricants Tester. It was desired to learn more about what lubrication qualities these machines would measure, and this perhaps led the way toward development of a test for predicting lubricant performance in high-speed, highly loaded gears, — the critical area of new design aircraft engines. The results of these lubrication studies are described in detail in Appendix V.

In the SAE machine the effects of varying operating conditions such as speed, shaft speed ratio, loading rate, and run-in schedule were first investigated. Based on this work, a test technique (designated

the SAE-SOD Test) was chosen for additional study. The operating conditions of this test are summarized in the following table:

SAE-SOD Test in SAE E.P. Lubricants Tester

Main Shaft Speed	1000 RPM
Shaft Speed Ratio	3.4/1
Test Cups	Timken T-48651
Run-in Schedule (several were used)	50 to 200 lbs. for 2 minutes
Loading After Run-in	Manual, stepwise, 50 lbs. at 10 second intervals.
Failure Load	Minimum load at which scuffing of test cups occurs.

This test was found to be sensitive to the viscosity and chemical structure of the lubricant, as shown in Appendix II Figure 16. Surface-active ingredients in the lubricant could also be detected, as shown in Figure 17. As depicted in Figure 18, the SAE-SOD appeared to correlate rather well with the IAE Gear Machine test. However, after Figure 18 was drawn, some contradictory results were obtained on two lubricants from the Petroleum Refining Laboratory at the Pennsylvania State College. In the SAE machine PRL 3313 gave 1300 lbs. failure load, while PRL3312 (similar composition of lower viscosity) did not fail up to 2000 lbs. load. It is difficult to explain these results when viscosity level is considered.

All of the data obtained in the work with the SAE machine are presented in Appendix I Tables 55 and 56. The effects of differences in test cups (batch to batch), shaft speed, loading rate, and run-in schedule are shown graphically in Appendix II Figures 19 through 25. This information is presented since it may be of value to other workers who wish to continue the development of this type of test.

Tables 57 and 58 show the limited amount of data obtained in the Shell 4-Ball E.P. Tester. There does not appear to be a viscosity function in this machine, but surface-active agents are readily detected.

V - CONCLUSIONS

The more important conclusions reached during these studies have been stated in previous reports and are reiterated below:

(1) Esters, in general, conform to some common rules concerning structure. Side-chain branching gives low pour points, but is detrimental to viscosity-temperature and viscosity-volatility characteristics. Unbranched esters have high pour points but good viscosity-temperature and viscosity-volatility properties. Optimum branching therefore gives the best combination of properties.

(2) Esters, in general, have very desirable combinations of properties, and it is apparent that ester-type synthetic lubricants of nearly any desired viscosity could be made from raw materials of potentially wide availability.

(3) Adipic, azelaic, and sebacic acids are the most readily available dibasic acids suitable for synthetic ester manufacture, while the petroleum derived Oxo alcohols appear to be the most available alcohols for ester production. The diesters of these straight-chain dibasic acids lead the field of esters suitable as lubricants for use at both low and high temperatures, from the standpoint of outstanding properties as well as potentially high availability. However, diesters of certain polypropylene glycols, in which the terminal groups are composed of straight-chain monobasic acids, are equivalent to dibasic acid esters in all the characteristics studied under this project. If this type of glycol ester is not deficient from some other performance standpoint, it represents a promising alternate source of synthetic oil base stock.

(4) Mono-esters with the optimum degree of branching should be useful lubricants when flash points of 300-325°F. are adequate but excellent low temperature properties are essential. Optimum branching can be obtained through the esterification of a straight-chain acid with a branched alcohol.

(5) Unlike other alcohols produced by the Oxo process, C₉ Oxo alcohol produced from diisobutylene is not suitable as a raw material for synthetic oils. The esters prepared from this alcohol invariably have unexplainably poor low temperature properties.

(6) A large number of esters do not have linear viscosity-temperature lines on an ASTM chart. Most deviations from linearity are upward at low temperatures; a few are downward. The only generalization which can be stated at present is that molecules of the "dense center" configuration give the downward curvature.

(7) The persistence of the liquid state at low temperatures is not accurately described by pour point for most esters. These materials supercool considerably below their actual melting point. Service experience with ester-type oils will disclose whether this supercooling can always be expected and relied on.

(8) Flash point is the simplest measure of ester volatility, but it is markedly influenced by relatively unimportant quantities of volatile contaminants. Vapor pressure is the most fundamental measure of volatility, but complex apparatus is required for this determination. Evaporation rate is probably the most realistic volatility measurement, and the results correlate with the fundamental property of vapor pressure.

(9) Significant variations in oxidation stability are obtained among different batches of the same ester (inhibited). The same is true, to a lesser degree, of thermal stability. Impurities are believed to be the major cause of these differences.

(10) The esters of carboxylic acids are stable to hydrolysis under the conditions of the MIL-L-6387 Hydrolytic Stability Test.

(11) Most esters show very little thermal decomposition up to at least 392°F. Significant exceptions are the dibasic acid esters of secondary alcohols, which have relatively poor thermal stability. However, diesters of certain polypropylene glycols, despite their secondary hydroxyl linkages, are thermally stable at least up to 455°F.

(12) The SAE E.P. Lubricants Tester is capable of measuring the load-carrying ability of synthetic lubricants. A promising test, which is sensitive to viscosity, chemical structure, and surface-active ingredients, has been developed in the SAE machine. However, further work is required before this test can be relied on to predict full-scale gear performance.

(13) The 4-Ball E.P. Test is sensitive to surface-active ingredients but not to the viscosity of the lubricant.

- (1) Decomposition theoretically possible is assumed to be complete breakdown to give the stoichiometric quantity of original acid.
- (2) No liquid sample remained at the end of the test. White crystals of adipic acid had sublimed to the cooler top of the thermal tube. A small amount of dark residue remained in the bottom of the tube. No actual determination of acidity was made.

APPENDIX III

FIFTH QUARTERLY
PROGRESS REPORT

I. DISCUSSION

Evaluation of materials suitable as synthetic lubricants has continued along the lines pursued during the first year's work under this contract. Data on several of the important lubricant properties have been expanded and are discussed in the following sections. As in the past, materials for evaluation which could not be procured from commercial suppliers were synthesized in the laboratory. Details of this phase of the work are not presented, since the laboratory preparation and treatment of esters has been discussed generally in previous reports.

A. Viscosity and Volatility Studies

The viscosity of a material at low temperatures and its volatility at high temperatures may, for some applications, determine the operating temperature range of this material as a lubricant. Mineral oils do not have particularly good viscosity-volatility properties. In this and several other respects, they do not meet the severe lubrication requirements of high power-output aircraft turbo-engines. Consequently, emphasis has shifted to synthetic lubricants for such applications. Because of its importance, the viscosity-volatility concept has received considerable attention in these synthetic lubricant studies.

Flash point determinations are subject to certain errors but are useful in describing approximate volatility levels. Flash point is likely to reflect the presence of a small quantity of volatile contaminant rather than the volatility of the lubricant itself. This point is illustrated in Appendix II Figure 5, which has been revised from earlier reports. The correlation of vapor pressure and flash point for the esters studied in this work gives some badly scattered points. This is improved, however, if we distinguish between materials procured commercially and those prepared in the laboratory. The esters prepared in the laboratory are distilled, so the volatile impurities are essentially removed. Esters sold as plasticizers undoubtedly do not receive this careful treatment. The difference between a distilled and a commercial ester does not appear in vapor pressure results, since the method used is designed to eliminate the effect of volatile impurities. However, the difference does show up in flash point determinations. The effect of these impurities has been confirmed for one commercial ester. Distillation of Plexol 244 (di-C₈ Oxo adipate) caused a significant increase in flash point but did not change the vapor pressure. This will be discussed further in Section I - E. It is this effect which causes the experimental data in Figure 5 to fit two distinct lines better than a single line. There is still considerable scattering of the points. This is believed to be largely due to the inherent inaccuracies of flash point determinations.

The vapor pressure data have been expanded to cover a number of additional esters. The vapor pressure-temperature relationships for these materials are plotted in the manner described in earlier reports in Appendix II Figures 9, 10, 11, & 12. A full description of the vapor pressure apparatus and method used is presented in Appendix IIIA. As mentioned previously, an important feature of this method is the distilling off of an initial portion of the sample to avoid errors due to volatile contaminants. This method may also lend itself to determination of the thermal stability of the sample. The vapor pressure-temperature lines in Figures 9, 10, 11, & 12 are extrapolated as straight lines. However, in the several cases shown where data have been obtained at high temperatures, the lines curve upward indicating thermal break-down to more volatile materials. More data over an extended temperature range are necessary before this test can be relied on as an indication of thermal stability.

Of interest in Figure 9 are the vapor pressure data on Complex Ester B. As described in previous reports, this material was prepared in the laboratory to give the structure --

Vapor pressure data were also reported previously for a similar material, Complex Ester A, having a Polyethylene Glycol 200 center esterified with sebacic acid and terminated with 2-ethylhexanol. The vapor pressures of these complex esters are higher than would be predicted for molecules of this size. These results tend to confirm the suspicion that "complex esters", even when carefully synthesized in the laboratory, may be expected to contain major amounts of side-reaction products. The data summarized below indicate that the simple diester of the dibasic acid involved is likely to be formed and have considerable effect on the vapor pressure of the "complex ester".

<u>Material</u>	<u>Number of Carbon Atoms</u>	<u>Vapor Pressure, mm. @ 400°F.</u>
Complex Ester A	44	0.45
Di-2-ethylhexyl sebacate	26	0.78
Complex Ester B	37	3.1
Di-C ₈ Oxo adipate	22	3.0

The viscosity-volatility properties of synthetic lubricants can be described conveniently with reference to an arbitrarily chosen index, used in previous work under this contract. The viscosity-volatility index is defined as the difference between the boiling point of the material at 2 mm. vapor pressure and the temperature at which it will thicken to 10,000 cs. viscosity. This temperature difference may have some practical significance as an indication of the acceptable operating temperature range possible with the lubricant. It has, however, an important shortcoming. Viscosity-volatility, as described by this temperature difference,

varies appreciably with viscosity, as shown in previous reports. Comparisons involving this index must therefore be made with some common viscosity level in mind.

Viscosity-volatility is one of the major properties in which ester lubricants have been shown to excel over mineral oils. However, it is of importance to note that esters do not represent the top of the scale with respect to this property. Studies by the California Research Corporation under Contract AF 33(038)-9831 have shown that certain tetra-alkyl silicates have superior viscosity-volatility properties, as well as outstanding viscosity-temperature properties. Furthermore, they are susceptible to thickening and V.I. improvement by the addition of silicone polymers. There may be problems connected with certain other properties of silicates, but if these are solved, silicate-base materials may represent an alternate means of increasing the availability of synthetic lubricants.

Since information on organo-silicon compounds was not included in the initial literature survey conducted under this contract, data on tetra-2-ethylhexyl silicate, taken from California Research Corporation reports, are compared in the following table with similar data on a typical diester, di-2-ethylhexyl adipate, and a Grade 1010 mineral oil. All three materials have similar viscosities at 210°F., but the viscosity-volatility index is appreciably poorer for the mineral oil than for either of the synthetic materials. The superiority of the silicate over the adipate is reflected in the lower vapor pressure and lower viscosity at low temperatures. If higher viscosity is required for satisfactory lubrication, the silicate can be thickened with silicone polymer to give about the same viscosity at -65°F. as the adipate, but much higher viscosity at high temperatures. Assuming the vapor pressure of the silicate-silicone blend remains the same as the base fluid, (it may actually decrease), the viscosity-volatility index of the blend is still better than that shown by the adipate.

Viscosity-Volatility Properties

Material	Viscosity, cs. @ °F.			Vapor Pressure, mm. @ 400°F.	Viscosity- Volatility Index, °F.
	210	-40	-65		
MIL-O-6081 Mineral Oil, Grade 1010	2.54	2500	--	--	311
Di-2-ethylhexyl adipate	2.36	833	4920	3.1	455
Tetra-2-ethylhexyl silicate	2.36	260	1320	1.3	506
Tetra-2-ethylhexyl silicate + 10% diethyl silicone (80,000 cs. @ 77°F.)	8.69	1250	4675	(1.3)	(485)

Among carboxylic acid esters, the diesters of dibasic acids were shown in previous work to have, generally, the best viscosity-volatility properties. There are now indications that certain types of diesters may

be better than others. It appears that esters of short, straight-chain (C_4 , C_5) dibasic acids have poorer viscosity-volatility characteristics than those of longer chain acids (C_6 - C_{10}) when compared at a given viscosity level. Although extensive vapor pressure data on maleates (C_4), succinates (C_4), and glutarates (C_5) have not actually been obtained in this work, it is possible to estimate vapor pressures (using Appendix II Figure 13) from the flash points given in literature for several of these materials. The viscosity-volatility index can then be determined as it is for the many adipates, azelates, and sebacates evaluated in this program. When this index is plotted against viscosity at -40°F ., as in Appendix I, Figure 26, the effect of acid chain length can be illustrated. Although the correlations for the maleates, succinates, and glutarates are based on just two or three points each, the data are firm enough to be directionally correct. They indicate that, for a given viscosity at -40°F ., as the acid chain length of the ester increases, volatility decreases faster than low temperature viscosity increases, thus improving the viscosity-volatility index. The effect becomes less and less pronounced, until between the C_9 and C_{10} acid chain lengths there appears to be no difference. This phenomenon is illustrated in the following table, summarizing the data in Figure 26 at the common viscosity of 1000 cs, at -40°F .

Viscosity-Volatility - Effect of Acid Chain Length

	<u>For an Ester of 1000 cs. Viscosity at -40°F.</u>				
	Maleates C_4	Succinates C_4	Glutarates C_5	Adipates C_6	Azelates and Sebacates C_9 and C_{10}
Viscosity-					
Volatility Index, $^\circ\text{F}$.	391	417	443	462	477

On the basis of this theory, the development of a diester lubricant with given viscosity requirements should favor where possible the longer chain acids, (and consequently lower molecular weight alcohols), for best viscosity-volatility properties. However, as other literature data show, this can be carried too far, since esters with extremely short-chain terminal groups generally have high melting points. Moreover, esters can never be chosen on the basis of viscosity-volatility alone. Among other criteria, availability is of prime importance, and adipic, sebacic, and azelaic acids (in that order) have been shown to be potentially the most available of the dibasic acids. Fortunately, the esters of these acids, as seen above, are in the upper viscosity-volatility range.

It has been previously postulated that the viscosity-volatility properties of dibasic acid diesters could be improved through the use of structures having the optimum degree of branching. As an example, mono- C_8 Oxo-mono- n -hexyl adipate was shown to have lower viscosity but a higher flash point than di- C_8 Oxo adipate. Flash points were

the only indication of volatility available at the time. However, as pointed out previously, flash points are subject to large errors, particularly when the esters evaluated have not all been refined to the same degree. It is not surprising, therefore, that this picture is revised somewhat, in the light of more recent vapor pressure data. The following table summarizes the viscosity-volatility data which are based on vapor pressures. The viscosity-volatility index is not shown, since it is misleading when compounds of significantly different viscosity levels are compared. Di-C₈ Oxo adipate is more viscous than di-2-ethylhexyl adipate but has a slightly lower vapor pressure, so that these materials are considered to have about equivalent viscosity-volatility properties. The mixed ester, mono-C₈ Oxo-mono-n-hexyl adipate, having less branching, appears less volatile than these plasticizer-grade diesters on the basis of flash point. However, it is more volatile on the basis of vapor pressure determinations, since they do not recognize the presence of minor contaminants in the plasticizers. Also, it is insufficiently branched to prevent crystallization at -65°F. Substitution of 2-ethylbutanol for n-hexanol in the mixed ester gives enough branching to avoid low temperature difficulties. But this branching, in turn, increases the vapor pressure. Therefore, the combination of viscosity and volatility obtained with mono-C₈ Oxo-mono-2-ethylbutyl adipate actually represents little improvement over that shown by di-C₈ Oxo- or di-2-ethylhexyl adipate. In fact, this mixed ester matches almost exactly the properties of di-sec. amyl sebacate, when flash points are ignored.

Viscosity-Volatility Properties of Diesters

Compound	Viscosity, cs. @ °F.			Flash Pt., °F.	Vapor Pressure, mm. @ 400°F.
	210	-40	-65		
Di-2-ethylhexyl adipate	2.36	833	4920	395	3.1
Di-C ₈ Oxo adipate	2.79	1040	6460	385	2.6
C ₈ Oxo, n-hexyl adipate	2.34	456	Cryst.	400	3.8
C ₈ Oxo, 2-ethylbutyl adipate	2.28	532	2830	390	6.0
Di-sec. amyl sebacate	2.27	528	2970	375	6.4

The above data illustrate that the structures obtained in diesters which utilize available alcohols such as C₈ Oxo or 2-ethylhexyl contain very nearly the optimum degree of branching already. It is difficult to improve their properties by the mixed ester route. These data also show that flash point may be misleading in comparisons of this sort.

Esters having polyhydric alcohol centers may also be of interest as a means for increasing the availability of synthetic lubricants. Particularly promising are the esters having polypropylene glycol centers

groups. Materials of this structure have properties which match those attainable with dibasic acid diesters. On the other hand, esters having polyethylene glycol centers seem to require branched chain terminal groups for satisfactorily low melting points, and these materials are markedly inferior to the dibasic acid esters. The superiority of the propylene glycol over the ethylene glycol esters is attributed to the position of the branching. It appears that the branching necessary to give low melting point glycol esters is least detrimental to viscosity-volatility and viscosity-temperature properties when it is present near the center of the molecule, rather than at the ends.

Dipropylene glycol di-n-octanoate has about the same viscosity at 210°F. as di-2-ethylhexyl adipate. Although its vapor pressure is somewhat higher, its low temperature viscosity is lower, thus giving viscosity-volatility properties which at least match those of the adipate. Triethylene glycol di-2-ethylhexanoate, having also about the same viscosity at 210°F. as these materials, has a lower vapor pressure but, because of a lower V.I., has much higher low temperature viscosity. Thus, this compound actually has poorer viscosity-volatility properties than either the adipate or the propylene glycol ester.

Viscosity-Volatility Properties - Glycol Diesters

Compound	Viscosity, cs. @ °F.			Vapor Pressure, mm. @ 400°F.
	210	-40	-65	
Di-2-ethylhexyl adipate	2.36	833	4920	3.1
Dipropylene glycol di-n-octanoate	2.37	647	3405	3.8
Triethylene glycol di-2-ethylhexanoate	2.35	1830	16,260	2.3

Di-C₈ Oxo adipate and tripropylene glycol di-n-octanoate show a similar comparison. In this case, the low temperature viscosities are about equivalent, but the glycol ester has a lower vapor pressure, resulting in slightly better viscosity-volatility properties. Tetraethylene glycol di-2-ethylhexanoate, again because of poor viscosity-temperature properties and the resulting high viscosity at low temperatures, is inferior to both these materials in viscosity-volatility. Evidence of excessive branching exists in tripropylene glycol di-2-ethylhexanoate. This material has very poor viscosity-temperature properties, and it is too unstable thermally to allow a satisfactory vapor pressure determination to be made.

(Data on following page)

Viscosity-Volatility Properties - Glycol Diesters

Compound	Viscosity, cs. @ °F.			Vapor Pressure, mm. @ 400°F.
	210	-40	-65	
Di-C ₈ Oxo adipate	2.79	1040	6460	2.6
Tripropylene glycol di-n-octanoate	2.76	1040	7000	1.75
Tetraethylene glycol di-2-ethylhexanoate	2.81	2980	30,980	1.3
Tripropylene glycol di-2-ethylhexanoate	2.64	3840	42,670	unstable

The viscosity level of these glycol esters can be varied by changing the size of either the glycol or the mono-basic acid employed. However, for the best combination of properties it appears that the center of the ester should be a propylene glycol, in which case the terminal groups must be straight chain. As another example, at a lower viscosity level, a satisfactory ester can be made from tripropylene glycol and caproic acid (normal C₆). This material is only slightly inferior to di-sec. amyl sebacate.

Viscosity-Volatility Properties - Glycol Diesters

Compound	Viscosity, cs. @ °F.			Vapor Pressure, mm. @ 400°F.
	210	-40	-65	
Di-sec. amyl sebacate	2.27	528	2970	6.4
Tripropylene glycol di-caproate	2.13	591	3570	6.3

On the basis of these results, there would be little or no degradation in viscosity-temperature or viscosity-volatility properties if a dibasic acid ester were replaced in a lubricant formulation by a polypropylene glycol ester. There are, of course, other properties to be considered before these materials can be regarded as an alternate supply source in the synthetic lubricant field. However, one expected drawback may be less serious than anticipated. The thermal stability of the propylene glycol esters, viewed with some doubt because of their secondary hydroxyl linkages, is surprisingly good up to 392°F. This will be discussed further in Section I - D. Other important properties of these esters have not yet been thoroughly evaluated, but serious deficiencies are not expected.

B. Low Temperature Studies

Low temperature viscosity and the persistence of the liquid state at low temperatures are important properties of a synthetic lubricant, if it is to perform satisfactorily in cold climates or at high altitude. Evaluation of the latter of these properties is difficult because of the tendency of esters to super-cool (sometimes!). Pour point determinations are therefore not reliable, and melting points, of course, can only be determined when the ester can be induced to crystallize. Methods for freezing these materials are being investigated. However, some esters have frozen when stored at -94°F . for 15 hours. Melting points have been obtained on these compounds and are presented along with some other low temperature properties in Appendix II Table 42.

Because of the limited nature of the melting point data available to date, specific conclusions regarding the effect of ester structure on this property are not possible. Several generalizations have already been made in previous reports. It was found that esters utilizing C₉ Oxo alcohol, produced by the Oxo process from diisobutylene (giving predominantly 3,5,5-trimethylhexanol), are generally high melting. The same is true of secondary alcohols, such as sec. hexyl or capryl alcohol, although di-sec. amyl sebacate is quite low melting. With reference to some melting point data reported in the literature, one further generalization is possible. The effect of ether-oxygen linkages in lowering the melting point can be seen in the table below. Di-butyl Cellosolve adipate, a straight chain diester containing two ether-oxygen atoms and the same number of carbon atoms as di-n-butyl sebacate, has a significantly lower melting point than the sebacate. Similarly, tetraethylene glycol di-caproate is better than butanediol-1,4-di-n-octanoate. Other structural differences in these compounds may also account for some of the difference in melting points, but the ether-oxygen atoms are believed to be chiefly responsible.

Melting Points

<u>Compound</u>	<u>Number of Carbon Atoms</u>	<u>Melting Point, °F.</u>
Di-n-butyl sebacate*	18	+20
Di-butyl Cellosolve adipate	18	- 3
Butanediol-1,4-di-n-octanoate*	20	+55
Tetraethylene glycol di-caproate	20	+ 1

Along with low melting points, it is desirable for synthetic lubricants to exhibit low viscosities at low temperatures. This characteristic is, of course, involved in the viscosity-temperature and viscosity-volatility properties of the lubricant. However, another factor may be

important. Certain esters have been shown in previous reports to deviate noticeably at low temperatures from the linear viscosity-temperature relationship usually obtained on an ASTM chart for other esters. Generally speaking, diesters containing ether-oxygen linkages and diesters produced from Oxo alcohols give undesirable upward curvature at low temperatures; "dense center" materials such as phthalates or pentaerythritol esters give downward curvature, a desirable deviation. It is felt that a study of the possible causes of this phenomenon may lead to a method for improving the properties of those esters showing an upward hook.

The change in ASTM Slope from 210/100°F. to 210/-40°F. is indicative of the magnitude of deviation from a linear ASTM viscosity-temperature relationship. Slope changes for a number of esters are presented in Appendix II, Table 42. There was reason to believe that the viscosity hook might be related to the separation of contaminants as a second phase at low temperatures. Cloud points were therefore obtained on these esters and are also presented in Table 42. However, the cloud point data do not follow any understandable pattern, and do not correlate with change in ASTM Slope values. Some of these cloud points undoubtedly reflect the presence of moisture. No attempt was made to dry the esters, since any moisture was also present during the viscosity determinations. Refinement of a sample of di-C8 Oxo adipate (Plexol 244) by stripping or distillation seems to cause erratic changes in cloud point, but does not affect the increase in ASTM Slope. Based on these results, it does not appear that the low temperature viscosity deviations are caused simply by the existence of a contaminant or second phase at low temperatures.

There does appear to be a rough correlation between the change in ASTM Slope and the melting point of the ester. Although the data are not firm, high melting esters generally seem to have the largest Slope changes, while the low melting materials have more nearly linear ASTM viscosity-temperature relationships. This suggests supercooling as a factor. In theory, however, truly supercooled liquids are believed to follow the same principles of flow as normal liquids, i.e., those at temperatures above their melting points. No satisfactory explanation can be given for this relationship of Slope change and melting point. It may be due merely to chance. It is illustrated in the following table, where data, taken from Table 42, on two similar diesters of sebacic acid and two similar glycol esters are compared. The low melting sebacate and glycol ester show negligible change in Slope, while the higher melting esters exhibit considerable upward curvature. The high melting point of tripropylene glycol di-n-octanoate is particularly difficult to understand, since branching and ether-oxygen atoms are both present in this molecule. But compared with the low melting dipropylene glycol ester of the same acid, it constitutes a striking, though possibly coincidental, example of the general relationship observed between melting point and change in ASTM Slope.

(Data on following page)

Low Temperature Properties

Compound	Melting Point, °F.	ASTM Slope Values		
		210/ 100°F.	210/ -40°F.	Difference
Di-sec. amyl sebacate	-108	0.756	0.755	-0.001
Di-sec. hexyl sebacate	+10	0.732	0.761	+0.029
Dipropylene glycol di-n-octanoate	-100	0.759	0.756	-0.003
Tripropylene glycol di-n-octanoate	+7	0.725	0.740	+0.015

C. Oxidation Stability Studies

Previous work has shown phenothiazine to be a satisfactory oxidation inhibitor for use in a study of the oxidation stability of various esters. For this evaluation a modification of the MIL-L-6387 Oxidation/Corrosion Stability Test (347°F.) is being employed. The neutralization number of the test sample is determined periodically until a sharp increase in acidity occurs. This indicates the stable life of the material under severe oxidizing conditions. A concentration of 0.3 wt. % phenothiazine has been chosen for the study of various esters in this test. This concentration appears to give a stable life level at which differences can be shown, but does not prolong the tests to an inconvenient length.

A very important factor which must be considered in this work is the effect of impurities on oxidation stability. Data reported by the Petroleum Refining Laboratory of the Pennsylvania State College show that a distilled grade of di-2-ethylhexyl sebacate (inhibited with phenothiazine) is more stable to oxidation than the less pure plasticizer grade. This is confirmed by the results shown in the following table, taken from Appendix II, Table 59. Differences in purity is also the likely reason for the variation in stable life (duplicate determinations) between two batches of di-C₈ Oxo adipate (Plexol 244). An attempt was made to remove impurities from this commercial ester by conventional means to learn if the oxidation stability could be thus improved. Unfortunately, before the difference between the two batches of this ester was known, the better of the two was chosen for this study. In this case, stripping, distilling, or charcoal treating did not improve stability. The stable lives of the treated samples appear somewhat lower than the untreated ester, but these variations may be within the repeatability range of the test. Not enough of these tests have yet been run to establish firmly what this repeatability range might be.

Oxidation Stability at 347°F.

(Each Ester Inhibited with 0.3 Wt. % Phenothiazine)

Compound	Refinement	Average Stable Life, Hrs.
Di-2-ethylhexyl sebacate (Plexol 201)	plasticizer grade	65
Di-2-ethylhexyl sebacate (Plexol 201W)	distilled grade	87
Di-C ₈ Oxo adipate (Plexol 244-Batch I)	plasticizer grade	45
Di-C ₈ Oxo adipate (Plexol 244-Batch II)	plasticizer grade	85
" " " " " " " "	stripped	75
" " " " " " " "	distilled	72
" " " " " " " "	distilled + charcoal treated	80

Data for several other esters procured from commercial suppliers are also presented in Appendix II, Table 59. However, comparisons based on these results are not reliable, since significant differences in the purities of these materials may exist. It is interesting, however, that an ester produced from a secondary alcohol (di-sec. amyl sebacate) appears reasonably stable to oxidation, at least at this temperature. It is believed that a comprehensive study of the oxidation stability of various ester types will require that each material tested be first given a common treatment.

D. Thermal Stability Studies

A variety of esters have been evaluated in a thermal stability test, in which the sample is held at 392°F. for 48 hours in a nitrogen atmosphere. The change in neutralization number occurring during the test is indicative of the extent to which the molecule has been thermally decomposed. Originally, viscosity change was also measured in this test. However, the change in viscosity was generally quite small, except for large polymers, which showed substantial viscosity decreases due to thermal break-down. The most recent thermal stability data are shown in Appendix II, Table 51. Neutralization number increases have been converted to % decomposition by assuming that any increase in acidity is due to the formation of the acid which was originally esterified. On this basis, 100% decomposition would represent complete break-down to give the stoichiometric quantity of the original acid. These assumptions most likely do not depict what actually happens, but they do provide a consistent basis for comparison of esters having known molecular weights.

As in the case of oxidation stability, the quality or purity of the ester may have a marked effect on its thermal stability. Several different samples of the same two diesters, di-C₈ Oxo adipate and di-C₈ Oxo sebacate, have been evaluated. As shown by the following data taken from Table 51, they may vary considerably in their resistance to decomposition at 392°F. Presumably the instability in certain cases is caused by some impurity with which the manufacturers need not be concerned when producing diesters for plasticizer applications. These impurities do not appear to show up simply as residual acidity in the ester, since decomposition does not line up with the initial neutralization numbers obtained on these materials.

Thermal Stability Studies

Compound	Initial Neut. No., mg. KOH/gm.	Neut. No. Increase, mg. KOH/gm.	Decomposition, %
<u>Di-C₈ Oxo adipate</u>			
Plexol 244 (Batch I)	0.35	0.17	0.06
Plexol 244 (Batch II)	0.14	0.09	0.03
Hardesty	0.23	1.43	0.47
PX-208	0.33	5.43	1.8
<u>Di-C₈ Oxo sebacate</u>			
Hardesty (Batch I)	0.70	1.07	0.41
Hardesty (Batch II)	0.19	4.69	1.8
PX-408	0.40	5.86	2.2

As in the case of oxidation stability, stripping, distilling, or charcoal treating did not improve the thermal stability of Plexol 244 (Batch II), which was already quite good. This particular ester, as pointed out before, was an unfortunate choice for these impurity removal studies. With the data now on hand, it appears that more information will be obtained by studying the effect of impurity removal using an ester such as the particular sample of PX-408, a material which appears deficient in both oxidation and thermal stability in its present form.

Even when the effects of impurities are taken into account, di-basic acid esters produced from secondary alcohols show a tendency toward less stability than the primary alcohol counterparts. Although the repeatability of this thermal stability test has not been adequately determined, the data shown in Table 51 indicate that esters of sec. amyl, sec. hexyl, and capryl (sec. octyl) alcohols undergo considerable degradation. Di-capryl adipate appears particularly bad, giving nearly 14% decomposition. It is surprising, therefore, that certain esters having polypropylene glycol centers seem quite stable, despite the secondary hydroxyl linkages. Several thermal stability tests have been run on each of the propylene glycol esters synthesized in this work. Results are shown in Table 51. When 2-ethylhexanoic acid is used, the resulting ester has borderline stability. This has been confirmed in vapor pressure determinations, where this excessively branched type of ester appears to decompose readily. However, when straight chain mono-basic acids (caproic, n-octanoic) are employed, the resulting propylene glycol esters have consistently shown good thermal stability. In fact, these esters have, in several tests, shown a slight decrease in acidity. The reason for this is not known, but it may indicate a thermal reaction which runs to completion rather than one which produces acidic materials that, in turn, may catalyze further decomposition.

E. Effect of Impurities on Ester Properties

Results of this study, discussed separately in preceding sections of this report, are summarized in Appendix II, Table 60. Attempts were made to purify a sample of di-C₈ Oxo adipate (Plexol 244) by conventional means to determine what effect purity might have on its properties. Three methods of refinement were used. One sample was stripped under vacuum to remove the first 5%; another was distilled at reduced pressure to obtain a 5-95% heart cut; the third consisted of a 5-95% heart cut which was treated with animal charcoal. The charcoal treatment has been found quite efficient in reducing residual acidity of esters, and it was desired to learn if it might provide some other benefits.

As disclosed by recent results, the particular sample of ester chosen for this study was already quite stable in the untreated form. Refinement therefore made no significant improvement in stability. This is not believed to be a true indication of what effect purification might have on the stability of an ester which is initially poor in this respect. Treatment of Plexol 244 by these means does result in one change in its properties which bears remembering. As shown in Table 60, stripping or distilling this material increases its flash point from about 380°F. to over 400°F. However, the vapor pressure remains essentially the same. This indicates that the vapor pressure method used in this work succeeds reasonably well in minimizing the effects of the volatile contaminants which cause the flash point lowering.

APPENDIX III A

METHOD FOR
VAPOR PRESSURE DETERMINATION

APPENDIX III A

A. Description of Vapor Pressure Apparatus and Method

1. Apparatus

The general appearance of the apparatus is shown in Figure 27. Details of the still and related parts are given in Figure 28.

The specially designed still head containing a built-in automanometer is patterned after the design recommended by Hickman and Weyert⁽¹⁾ for the accurate distillation of samples ranging from 5 to 100 grams. The openings to the bulbs of the column are relatively large to minimize pressure drop of entering vapor, to allow excellent drainage, and to remove superheated vapors. The automanometer operates directly from the wall of the expansion of the column. The still is connected to a receiver, a cold trap, a manometer, and a surge tank which in turn is connected by stopcocks to a vacuum pump and to a supply of dry nitrogen. The glass tubing connecting the various parts of the apparatus is constructed from 20 mm. tubing.

The thermometric system consists of a calibrated iron-constantan thermocouple, a type K potentiometer, and a suspension type galvanometer.

The pressure of the permanent gas is measured by means of a three-scale McLeod type gauge (Todd Universal Vacuum Gauge obtained from Todd Scientific Company, Springfield, Pennsylvania).

The Dubrovin gauge, while not an essential part of the apparatus, is useful as a continuous indication of the pressure of the system and as an aid while bleeding in the proper amount of nitrogen into the system.

The still is heated with a Glascol heater. Excessive bumping is prevented by means of a magnetic stirrer.

For boiling points below 100°C., merely insulating the upper part of the still pot and column with asbestos is sufficient to minimize condensation so that reflux and fractionation may be prevented. For temperatures above 100°C., heat should be applied to the outside of the upper part of the still pot and column in an amount equal to that lost by radiation.

2. Procedure

The apparatus is assembled as shown in Figures 27 & 28. The thermocouple is mounted as shown in Figure 28. The glass sheath should be coincidental with the center line of the column, and the tip of the encased thermocouple should extend to the same level as the lower outlet of the automanometer. All stopcocks, ball joints and standard tapered

FIGURE 27

GENERAL APPEARANCE OF THE
VAPOR PRESSURE-BOILING POINT APPARATUS

FIGURE 28

APPARATUS FOR VAPOR PRESSURE - BOILING POINT MEASUREMENTS

FIGURE 28 (continued)

joints are lubricated with a thin film of Apiezon N or other suitable high vacuum type grease. The stopcock and ball joint leading from the still pot to the receiver should be lubricated with a silicone high vacuum grease.

The entire apparatus is evacuated and tested for leaks by appropriate means. The system is returned to atmospheric pressure by admitting dry nitrogen. Fifty milliliters of the liquid under investigation is then pipetted into the bottom of the still into which a magnetic stirring bar has previously been placed. A sufficient amount of the liquid is added to the automanometer through the top outlet in order to set the zero mark on the sliding scale attached to the automanometer. The ball joint is attached to the top of the still and the thermocouple is replaced.

Stopcocks 1 and 4 are closed to isolate the still and receiver from the rest of the apparatus. The magnetic stirrer is turned on and the dissolved air and moisture in the sample are removed by evacuating through stopcock 3. Low heat may be applied to facilitate their removal.

Stopcock 3 is then closed and the rest of the apparatus evacuated through stopcock 4. The trap is immersed in liquid nitrogen. After closing stopcock 4, an appropriate amount of dry nitrogen to indicate a pressure of approximately 1 mm. on the Dubrovin gauge is bled into the system. The still is then connected with the rest of the apparatus by opening stopcock 1.

Heat is gradually applied to the still pot and, when the condensation of the liquid is visible in the lower end of the condenser, it is adjusted to a reasonable boiling rate. The condensate is allowed to collect in the annulus and flows back down the column. The temperature of the jacket surrounding the column is adjusted to a temperature about 10°C. below the boiling point if it is above 100°C. As soon as a steady, slow boil-up rate has been achieved, simultaneous readings are taken of the vapor temperature, the pressure of the permanent gas by means of the McLeod gauge, and the automanometer pressure. Several sets of data are recorded until successive readings are essentially constant. After equilibrium is established, several milliliters of the condensate are removed into the receiver through the side arm attached to the annulus. This procedure serves to remove any traces of low boiling condensable impurities present. The process of recording the necessary data after equilibrium is again established is repeated until successive readings are essentially constant. For a pure substance, the two sets of readings should be practically identical.

For further measurements at higher pressures, the heating is discontinued, and more dry nitrogen gas is charged into the system to the desired pressure. The whole process given above is repeated at pressures of 2, 3, and 4 mm.

The vapor pressure-temperature relation is obtained graphically by plotting the logarithm of the pressure against the inverse of the absolute temperature. All four points should fall in a straight line. By extrapolation, the vapor pressure at other temperatures can be obtained.

B. Results and Conclusions

The procedure outlined above was primarily designed for the measurement of vapor pressures and boiling points of high boiling or difficultly volatile pure liquids of limited thermal stability. It may be extended with modifications to include mixtures of these types of substances. However, the method is also applicable to high boiling compounds which are thermally stable.

This equipment will give reliable results between 0.03 mm. and 5 mm. pressure. Above this range, accurate measurements are rather difficult to obtain due to excessive bumping and splashing and, below this range, due to the fact that the random velocity is small compared with the forward velocity of the vapor molecules and by the interdiffusion between the vapor and residual gas.

If the thermometer is located in the vapor phase, the vapor, although it may be somewhat superheated when it is formed, soon cools and condenses. This temperature of condensation at slow rates of distillation is the true boiling point at the prevailing pressure when the liquid is absolutely pure and is also not affected by bumping of the liquid.

The absolute accuracy of the procedure may be established by determination of the boiling points at these low pressures of a relatively high boiling liquid which is thermally stable and by extrapolation of the vapor pressure-temperature relationship, the true boiling point at atmospheric pressure may be calculated. This result can then be compared to the best literature data or determined. However, a straight line obtained by plotting the logarithm of the pressure against the inverse of the absolute temperatures is indicative of the accuracy.

To test the accuracy and reproducibility of this method, it was applied to the determination of the vapor pressure-temperature relationship of pure n-dibutyl phthalate by two analysts. The results obtained, plotted graphically, are shown in Figure 29. By extrapolation, the boiling point at exactly 1 mm. pressure was found to be 143°C. This compares favorably with the best literature values of 143°, 145° and 144°C.

FIGURE 29

APPENDIX IV

SIXTH QUARTERLY
PROGRESS REPORT

I. DISCUSSION

Work pursued under this contract has been directed toward a study of the properties of synthetic lubricants, in particular, the carboxylic acid esters. The properties which have been investigated most include the following:

1. Viscosity-temperature
2. Viscosity-volatility
3. Melting and pour point
4. Stability (oxidation, hydrolytic, chemical and thermal)
5. Lubrication.

Those materials which have a good combination of these properties are considered to be very promising lubricants. However, other more specific properties may also be necessary depending upon the service to which the lubricants are to be subjected. This study has dealt primarily with the evaluation of materials suitable as components or bases for synthetic lubricants. No attempts have been made to formulate finished blends. The work has continued along the lines discussed in earlier reports. A large number of known and commercial synthetic esters have been evaluated. Data on most of the important lubricant properties mentioned above have been enlarged and several types of esters, which the literature indicates to be promising, have been synthesized to determine their relative position in this field. The results obtained during this quarter, and concerned mainly with expanding existing data on esters containing ether oxygens and esters of the dense center type, are discussed in the following sections.

A. Viscosity-Temperature Characteristics and General Properties

The physical properties of all ester materials either purchased from commercial suppliers or synthesized in the laboratory and evaluated since the first yearly report are presented in Appendix II Tables 38 & 39. The viscosity-temperature relationships are shown over the range of 210 to -65°F. by ASTM slope, Dean and Davis V.I., and Hardiman and Nissan V.I. This latter V.I. system(1) gives a more realistic picture of viscosity-temperature properties by avoiding the irregularities normally experienced at high V.I. levels when the Dean and Davis V.I. system is used. Other general data to be found in Tables 38 & 39 and discussed in the following paragraphs include neutralization numbers, flash, fire, pour, melting points, and vapor pressure data.

1. Monoesters Containing Ether Oxygen

Synthetic lubricants having extremely low viscosities can be made from monoesters. These may find use as special aircraft instrument oils, where low viscosity and low volatility along with moderately good high temperature properties are required. Monoesters could also find application where mechanical lag or sight glass fogging are problems, as well as in hydraulic fluids and as bases for low temperature greases. Earlier work on monoesters described in the literature showed that excessive branching gave poor viscosity-temperature characteristics and high volatility (low flash points), whereas no branching presumably gave high melting materials. The optimum degree of branching was found to be obtained when only one portion of the ester was branched -- either the alcohol portion or the acid portion, but not both. Furthermore, the C₁₆ to C₁₈ materials with their ester group near the center of the molecule showed the best monoester properties.

When similar monoesters are made from alcohols containing ether oxygen atoms (i.e., Carbitols, Dowanols, etc.) poorer viscosity-temperature characteristics result. As shown in Appendix Table 38 and in the summary table below, isopropoxyethoxyethyl n-octanoate (Dowanol 18 n-octanoate) is not sufficiently branched to give a satisfactory low pour point. The 2-ethylbutoxyethoxyethyl caproate (2-ethylbutyl Carbitol caproate), on the other hand, having the same 210°F. viscosity does have sufficient branching to give a very low pour point. In viscosity-temperature properties these oxy esters are nearly equivalent to the excessively branched C₈ Oxo ester wherein branching occurs on both sides of the ester group. They are, however, poorer than the optimum branched C₈ Oxo pelargonate. Like most monoesters, they show a tendency toward downward curvature when plotted on the ASTM viscosity-temperature chart but the changes, as shown by the ASTM slopes, are much smaller than those shown by the non-ether-oxygen monoesters so that essentially a straight line results. It will be noted that the only beneficial effect of the ether oxygen is to increase the flash point. This appears to be real and will be discussed later under viscosity-volatility characteristics.

(Data on following page)

Viscosity-Temperature Properties - Monoesters

Monoester	Viscosity Cs. At °F.			ASTM Slope 210°F. to		Flash Pt., °F.	Pour Pt., °F.
	210	-40	-65	100	-65

2-Ethylbutoxyethoxyethyl caproate	1.367	114	501	0.826	0.828	330	<-75
C8 Oxo pelargonate	1.374	78.8	259	0.810	0.785	305	<-75
C8 Oxo C9 Oxoate	1.390	103	410	0.827	0.810	285	<-75

* Slope 210/-40°F.

2. Monoesters Versus Diesters

The C₂₁ monoester, C₁₃ Oxo 3,5,5-trimethylhexanoate, were shown in AF Technical Report 6663 to be inferior to dibasic acid diesters of equivalent carbon content. Its poor showing at low temperatures is undoubtedly due, in part at least, to the terminal butyl group in the acid portion. More recent data for other monoesters, C₁₃ Oxo C₁₃ Oxoate and n-hexyl C₁₃ Oxoate, confirm the earlier observation that low pour monoesters in the C₁₈ to C₂₆ range are inferior in viscosity-temperature properties to dibasic acid diesters of the same carbon content or 210°F. viscosity. This also holds generally for glycol diesters although here a number of exceptions exist, especially when they are compared with a monoester having nearly optimum branching (n-hexyl C₁₃ Oxoate). The presence of the second ester linkage in both types of diesters is particularly effective in lowering the volatility (raising the flash point). The monoesters, C₁₃ Oxo C₁₃ Oxoate and n-hexyl C₁₃ Oxoate, are compared in the following table with dibasic acid esters having the same 210°F. viscosity and with glycol diesters having approximately the same carbon content. The superior low temperature viscosities of the dibasic acid diesters are particularly noteworthy.

(Data on following page)

Monoesters Versus Diesters

	Carbon Content	Viscosity, Cs. @ °F			ASTM Slope 210/100°F. H&N V.I.		Flash Pt., °F.
		210	-40	-65			
C ₁₃ Oxo C ₁₃ Oxoate	C ₂₆	3.38	7230	76500	0.775	115	405
Di-2-ethylhexyl sebacate	C ₂₆	3.39	1480	8380	0.693	150	430
Tripropylene glycol di-n-octanoate	C ₂₅	2.76	1040	7000	0.725	152	415
n-Hexyl C ₁₃ Oxoate	C ₁₉	1.74	307	1480	0.814	157	315
Di-3-methylbutyl adipate	C ₁₆	1.73	165	650	0.778	173	325
Diethylene glycol di-2-ethylhexoate	C ₁₈	1.97	1150	8580	0.842	129	360

3. Diesters Containing Ether Oxygen

There are four effects noted in diesters derived from alcohols containing ether oxygen, known commercially as Cellosolves, Carbitols, and Dowanols. As shown in the summary table below with data taken from the literature, the addition of ethylene oxide to C₉ Oxo alcohol results in (1) greater viscosity, (2) increased Dean and Davis viscosity indexes, (3) higher flash points, and (4) poorer pour points. It will be noted that the optimum viscosity-temperature relationship and flash point consistent with a good pour point are obtained when about two ethylene oxide units are added.

Effect of Ethylene Oxide on Diester Properties

Adipate (Diester)		Viscosity,		ASTM	D&D	H&N	Flash	Pour
		Cs. @ °F.	Slope	210/				
		210	100	100°F.	V.I.	V.I.	Pt., °F.	Pt., °F.
C ₉	Oxo (from diisobutylene)	3.21	12.7	0.728	136	142	415	<-98
C ₉	Oxo + 1 m. Ethylene Oxide	4.30	18.3	0.678	165	144	420	-82
C ₉	Oxo + 2 m. " "	5.74	27.4	0.652	154	144	465	-72
C ₉	Oxo + 4 m. " "	7.72	40.9	0.622	147	140	440	-62
C ₉	Oxo + 6 m. " "	10.0	54.1	0.591	148	144	435	-36

The changes resulting from the addition of ethylene oxide units are due mainly to the increased molecular weight but they also reflect the effect of the ether oxygen, which becomes more pronounced with the lower alcohol diesters, where the alkylene oxide portion constitutes a greater proportion of the molecule. As shown in the table below with esters of low molecular weight alcohols, the alkylene oxide actually improves the pour points but this effect diminishes as successive alkylene oxide units are added. The effect of ether oxygen in raising the viscosity level and lowering the pour point is shown by comparing the adipate of butyl alcohol + 2 mols of ethylene oxide with n-octyl adipate, both having the same carbon content and straight chain structure. Propylene oxide is shown to have an effect similar to ethylene oxide. The properties of the propylene oxide derivatives of isopropanol are compared below with those of di-sec. hexyl and di-C₉ Oxo adipates, which have similar viscosities but lack the ether oxygen. The sec.-hexyl adipate is shown to be inferior while the C₉ Oxo adipate is superior to the ether oxygen counterparts.

Effect of Alkylene Oxides on Diester Properties

Adipate (diester)	Viscosity,		ASTM			Flash	Pour
	Cs. @ °F.		Slope			Pt.,	Pt.,
	210	100	210/ 100°F.	V.I.	H&N V.I.	°F.	°F.
n-Butyl	1.49	3.68	0.748	--	--	340	-13
n-Butyl + 1 m. Ethylene Oxide	2.24	7.31	0.755	129	154	390	-40
n-Butyl + 2 m. Ethylene Oxide	3.47	13.3	0.694	158	145	450	<-35
n-Octyl	2.85	8.75	0.652	187	170	420	+39
Isopropyl	1.16	2.92	0.863	--	--	225	+30 (MP)
Isopropyl + 1 m. Propylene Oxide	2.08	6.99	0.796	102	147	325	<-75
Isopropyl + 2 m. Propylene Oxide	3.52	14.7	0.724	137	138	360	-65
Sec.-Hexyl	1.81	5.79	0.822	--	149	305	+50 (MP)
C ₉ Oxo	3.21	12.7	0.728	136	142	415	<-98

To expand the literature data on the properties of oxygen containing esters, several compounds were synthesized from alcohols containing two ethylene oxide units. Secondary alcohols were selected since their alkylene oxide derivatives might serve as a means of increasing the availability of synthetic esters. By this means a large number of low cost, readily available alcohols, which otherwise are not suitable because their esters are thermally unstable, can be utilized. Several of these Carbitol type diesters are compared in the summary table below with promising diesters having equivalent 210°F. viscosities. Complete data are given in Appendix Table I. It will be noted that diisopropoxyethoxyethyl adipate is a perfect match for di-2-ethyl-hexyl azelate in flash, pour, ASTM slope, V.I. and viscosities at the higher temperature levels. However, at low temperatures the viscosities and ASTM

slopes increase markedly revealing its inferior viscosity-temperature characteristics over the full temperature range. Dicaproyethoxyethyl adipate, which utilized capryl alcohol, a by-product of sebacic acid manufacture, appears to have somewhat better viscosity-temperature characteristics than C₁₀ Oxo sebacate based on the high temperature viscosities, but here again the tendency of the ether oxygens to cause an upward hook (increased ASTM slope) becomes evident at low temperatures. Similar diesters made from a primary alcohol base (di-2-ethylbutyl Carbitol adipate) appear to be in no way superior to the secondary derivatives.

Comparison of Dibasic Acid Diesters With and
Without Ether Oxygen

(All Pour Points are Less Than -75°F.)

Di-2-ethylbutyl Carbitol Adipate	3.686	40310	151	0.679	0.730	0.743	440
Di-C ₁₀ Oxo Adipate	3.598	23000	146	0.702	0.727	0.728	450

Most secondary alcohols tend to give diesters having high melting or pour points. The conversion of these alcohols to alkylene oxide derivatives provides a useful means by which satisfactory low pour materials can be obtained from these otherwise unattractive alcohols. This is considered to be an important advantage which can be cited for these materials, along with the improved thermal stability which will be discussed in Section E. As shown in the table below, dicapryl and diisopropyl adipates are transformed by the use of alkylene oxides into products having considerably better viscosity-temperature, flash and pour point characteristics.

(Data on following page)

Properties of Diesters Utilizing Secondary Alcohols
and Their Derivatives

4. Glycol Diesters Containing Ether Oxygen

Esters derived from glycols by reaction with monobasic acids have been found, in general, to be inferior to dibasic acid diesters. Several polypropylene glycol diesters were shown in the last quarterly report to be equivalent to dibasic acid diesters of the same viscosity and carbon content. These were dipropylene glycol di-n-octanoate, and tripropylene glycol di-n-octanoate and dicaproate. It will be noted that all of these esters require straight chain acids which may be in short supply in time of national emergency. These esters may serve, however, as a possible alternate supply of lubricant materials along with dibasic acid diesters. The straight chain C₉ pelargonic acid which is available commercially as a by-product from azelaic acid manufacture probably would not become short in an emergency but it does not give a satisfactory ester with tripropylene glycol. As shown in the Appendix Table 40 and in the summary table below, tripropylene glycol dipelargonate is inferior in viscosity-temperature properties to similar diesters made from shorter straight chain acids. The reason for the crystalline formation and consequently poor showing of the pelargonate ester is probably associated with the low purity of the commercial pelargonic acid employed.

Tripropylene Glycol Diesters

(<-75°F. Pour Points)

<u>Tripropylene Glycol Diester</u>	<u>Viscosity, Cs. @ °F.</u>			<u>ASTM Slope</u>		<u>H&N V.I.</u>	<u>Flash Pt., °F.</u>
	<u>210</u>	<u>-40</u>	<u>-65</u>	<u>210/100</u>	<u>210/-40</u>		
Dipelargonate	2.900	1178	Crystals	0.725	0.732	140	420
Di-n-octanoate	2.756	1040	7000	0.725	0.740	152	415
Dicaproate	2.134	591	3572	0.775	0.784	153	395

It will be noted that the tripropylene glycol diesters exhibit the upward viscosity-temperature hook characteristic of esters containing ether oxygens. Dipropylene glycol di-n-octanoate, on the other hand, gives a downward curvature which permits this ester to surpass many others diesters in viscosity-temperature properties throughout the temperature range investigated (-65 - 210°F.). This unusual but desirable behavior may possibly be due to some tendency for the glycol portion of this diester to form a pseudo ring or loop, giving rise to the dense center configuration which has been found associated with this downward curvature in many other instances. As shown below, certain other glycol diesters exhibit the same tendency. In the three cases cited a 1,5-glycol is involved which would be optimum for permitting the formation of a strain free ring or loop. Insufficient data are available to show whether polymethylene glycols other than the 1,5-type behave similarly.

Unusual Viscosity-Temperature Properties of
Certain Glycol Diesters

<u>Material</u>	<u>ASTM Slope, 210°F. to</u>		
	<u>100°F.</u>	<u>-40°F.</u>	<u>-65°F.</u>
Dipropylene glycol di-n-octanoate	0.759	0.756	0.752
Pentanediol-1,5 di-2-ethylhexoate	0.829	0.817	0.807
2-Ethoxymethyl-2,4-dimethyl pentanediol-1,5 dicaproate	0.781	0.776	0.776
2-Ethoxymethyl-2,4-dimethyl pentanediol-1,5-di-2-ethylhexoate	0.815	0.813	--

It would appear from these data that dipropylene glycol dipelargonate, which should likewise exhibit downward curvature, might possess reasonably good viscosity-temperature characteristics, and could be made from readily available materials.

Polyethylene glycols, like polypropylene glycols, can be produced on a much larger scale than they are now being made commercially. Their application to synthetic ester lubricants, therefore, would be desirable at least from an availability standpoint. The use of polyethylene glycols in diesters has not been considered very promising since poor viscosity-temperature characteristics are obtained with branched chain acids and high pour materials are produced with straight chain acids, according to the literature. It was observed in the work on Carbitol type diesters and in previous work that the presence of ether oxygen tended to lower the pour points of diesters in which the alkylene oxide portion constituted a sizeable

proportion of the molecule. Several diesters were synthesized to expand the existing data, especially at low temperatures, on compounds of the glycol diester type. Literature references indicate Polyethylene Glycol 200 and tetraethylene glycol would give better diester properties than lower polyethylene glycols. This is undoubtedly due to the fact that they are similar in carbon content to octanediol-1,8 and would give diesters in the C₂₂-C₂₆ range wherein the diesters having the best properties have been found. Low pour points would be anticipated for the diesters of these glycols, because the three ether oxygens in the glycol portion should have appreciable effect when not masked by the size of the monobasic acid used. As is shown in Appendix Table 40 and in the table below, low pour diesters can be obtained with straight chain acids. Thus, with Polyglycol 200 and caproic acid a pour of -65°F. is obtained, compared with +60 for ethylene glycol di-n-octanoate. Lower pour diesters can be obtained with very little sacrifice in viscosity-temperature characteristics by introducing a moderate amount of branching, as is shown for Polyglycol 200 mono-2-ethylbutyrate mono-caproate. The same result could possibly be obtained by employing a slightly higher molecular weight polyethylene glycol (more ether oxygens), although this has not been demonstrated. The viscosity-temperature characteristics of these glycol diesters are inferior to dibasic acid diesters over the full temperature range (210 to -65°F.) because of their upward hook at low temperatures. The flash points are high compared with di-2-ethylhexyl azelate and hexane-diol-1,6 di-n-octanoate. This difference may reflect in part the degree of purification or stripping, but it is probably also associated with the presence of the ether oxygens.

Viscosity-Temperature Properties - Glycol Diesters

	Viscosity, Cs. @ °F.		ASTM Slope 210/°F.		H&N V.I.	Flash Pour Pt., Pt., °F. °F.	
	210	-40	100	-40		°F.	°F.

5. Dense-Center Polyesters

Polyesters in which the acid or alcohol portions appear to emanate from a common source or dense center generally exhibit a desirable downward curvature of their ASTM viscosity-temperature relationship at low

temperatures. These include esters of tri or tetrahydric alcohols such as triethanol amine, trimethylolpropane, and pentaerythritol. Aconitates, dimerates, phthalates, phosphinates, phosphonates, phosphates, phosphites, silicates, and the like also show the same phenomenon. The esters of pentaerythritol and trimethylolpropane are of special interest in this work since they have fairly attractive properties and can be made from available materials (acetaldehyde, butyraldehyde, formaldehyde and mono-basic acids). They could possibly serve, therefore, as alternates for dibasic acid esters where moderately good viscosity-temperature characteristics would suffice. Unfortunately, these polyhydric alcohol esters of straight chain acids have undesirably high melting points. As shown in Appendix Table 40 and in the summary table below, introduction of some branching eliminates the high melting point difficulties but, as might be expected, imparts poorer viscosity-temperature characteristics, as indicated by lower H&N V.I. and higher low temperature viscosities. Pentaerythritol dicaproate di-2-ethylbutyrate appears to be excessively branched. It is believed that the pentaerythritol tricaproate mono-2-ethylbutyrate would provide the optimum degree of branching. Trimethylolpropane dicaproate mono-2-ethylbutyrate has about the optimum amount of branching for a trimethylolpropane triester; hence, no further improvement can be expected. At the suggestion of the project engineer, another polyester, tri-n-butyl aconitate, was given a preliminary evaluation, since the American Sugar Refining Company proposes to recover reasonably large quantities of aconitic acid (1,2,3-propenetricarboxylic acid) from molasses. As shown in Appendix Table 38 and in the summary table below, this aconitate does not have outstandingly good viscosity-temperature properties but is similar in this respect to the pentaerythritol and trimethylolpropane polyesters. It is unsaturated and consequently has poor oxidation stability. It does not crystallize at low temperatures but has a lower flash point than diesters of similar viscosity.

(Data on following page)

Dense-Center Polyesters

Polyester	Viscosity, Cs. @ °F.		ASTM Slope 210/°F.		H&N V.I.	Flash	Melting
	210	-40	100	-40		Pt., °F.	Pt., °F.
Pentaerythritol tetra- caproate	4.133	4656	0.734	0.717	125	470	+21
Pentaerythritol di- caproate di-2-ethyl- butyrate	4.660	16400	0.764	0.746	106	470	WNC
Trimethylolpropane tri-n-octanoate	4.046	3276	0.717	0.703	133	485	+18
Trimethylolpropane di- caproate mono-2-ethyl- butyrate	3.163	2959	0.780	0.761	121	415	WNC
Tri-n-butyl aconitate	2.438	1509	0.829	0.799	116	370	WNC
Di-2-ethylhexyl Adipate	2.362	833	0.770	0.774	147	395	-90

WNC: Would not crystallize after 15 hours at -94°F.

B. Viscosity-Volatility Characteristics

In order for a lubricant to withstand the extremes in temperature anticipated for newer design turbine type aircraft engines, the lubricant must combine low volatility at high temperatures with low viscosity at low temperatures. Mineral oils do not possess a satisfactory combination of these properties and therefore have poorer viscosity-volatility characteristics than desired for these engines. In contrast, ester-type synthetic lubricants are quite good in this respect. In the absence of impurities, the flash points of synthetic lubricants are influenced to a large extent not only by the number of carbon atoms and branchiness but also by the type, position, and number of functional groups present in the molecule. The flash points of mineral oils, on the other hand, depend generally only on carbon chain length and branchiness since no functional groups are present. Flash point determinations are used to give a fair indication of volatility in mineral oil work but since they are generally subject to considerable error, they should not be relied upon to give an accurate indication of volatility for non-hydrocarbon synthetic lubricants. Actual vapor pressure determinations have been used to measure the volatility of the esters evaluated in this work. The method used is that described by Hickman and Weyerts(2) and is presented as Appendix III A. In brief, the experimental data obtained at 0.4 to 8 mm. pressure are plotted as $\log V.P.$ versus $1/(t+230)$ where t is in $^{\circ}C$. A straight line results from which fair values for any vapor pressure at any temperature can be obtained. Vapor pressure-temperature and viscosity-volatility data of all compounds evaluated in this program are tabulated in Appendix Tables 43 and 44. The viscosity-volatility characteristics of synthetic lubricants were discussed in some detail in Appendix III. Additional work has been concerned with diesters containing ether oxygen atoms, and is discussed in the following sections.

1. Monoesters

As discussed above, the volatility of non-hydrocarbon synthetic lubricants is influenced to a great extent by several factors. The degree and position of branchiness appears to be important. Comparison of monoesters (Appendix Table 43) shows that branchiness occurring on only one side of the ester linkage, preferable in the alcohol portion(3), is optimum,

(2) Hickman and Weyerts, J. Am. Chem. Soc., 52, 4714 (1930).

(3) Recent brochure on Esters (Carbide and Carbon) shows n-hexyl 2-ethylhexanoate to have higher volatility than 2-ethylhexyl caproate.

giving less volatile esters than when the branching is on both sides of this group. Thus, C₈ Oxo n-octanoate has only half the vapor pressure of 2-ethylhexyl 2-ethylhexanoate although both esters have the same carbon content. Since the viscosity is also improved by this selective distribution of branchiness, the C₈ Oxo n-octanoate has the better viscosity-volatility properties. The presence of ether oxygen also has an effect. The introduction of two ether oxygens tends to lower the volatility. As shown in the table below, isopropoxyethoxyethyl n-octanoate and 2-ethylbutyl Carbitol caproate have lower vapor pressures at 400°F. than C₈ Oxo pelargonate, yet all three esters have the same 210°F. viscosities and about the same degree of branchiness. However, because of their slightly poorer low temperature properties these ether-monoesters are considered to have viscosity-volatility properties which are essentially equivalent to the C₈ Oxo pelargonate.

Viscosity-Volatility Properties of Monoesters

Monoester	Viscosity, Cs. @ °F.			Flash Pt., °F.	Vapor Pressure, mm. @ 400°F.	Viscosity- Volatility Index
	210	-40	-65			
Isopropoxyethoxyethyl n-octanoate	1.363	104.1	Solid	315	50	--
2-Ethylbutyl Carbitol caproate	1.367	113.9	501	330	35	382
C ₈ Oxo pelargonate	1.374	78.8	259	305	60	373

A rough measure of viscosity-volatility properties is given by the viscosity-volatility index. This is an arbitrarily chosen index and is defined as the difference between the boiling temperature of the material at 2 mm. and the temperature at which it has a 10,000 cs. viscosity. A shortcoming of this index is its variation with viscosity, necessitating comparisons at common viscosity levels. Where the material is a solid at the lower temperature, as is the case with isopropoxyethoxyethyl n-octanoate, the viscosity-volatility index has no real significance. For reference, however, this index has been calculated for all materials evaluated and the data are compiled in Appendix Tables 43 and 44.

2. Dibasic Acid Diesters

The Carbitol type diesters are considered to be poorer in viscosity-volatility properties than conventional diesters not having ether oxygens. These ether-diester (of dibasic acids) have generally lower volatilities, but they also have considerably higher viscosities at low temperatures. As shown below with data taken from Appendix Tables 43 and 44, diisopropoxyethoxyethyl adipate is at least equivalent to di-2-ethylhexyl azelate in all the properties examined except low temperature

viscosity, where it is inferior (26,500 cs. versus 6260 at -65°F.). Di-heptyl Carbitol and di-2-ethylbutyl Carbitol adipates likewise have lower vapor pressures at 400°F. and higher low temperature viscosities than the conventional diesters with which they are compared. Comparison of 2-ethylbutyl Carbitol adipate with esters having about the same vapor pressure at 400°F. (di-C₁₀ Oxo sebacate; trimethylolpropane tri-n-octanoate), shows the large effect that the ether oxygens have on increasing the low temperature viscosity. This factor tends to offset the advantages of the low volatilities obtainable with this type of compound. Their usefulness may lie chiefly in applications where low temperature viscosity requirements are not restrictive, or they may find use as blending components.

Viscosity-Volatility Properties of Diesters

Material	Viscosity, Cs. @ °F.			Flash Pt., °F.	Vapor Pressure, mm. @ 400°F.
	210	-40	-65		
Di-isopropoxyethoxyethyl Adipate	2.948	2212	26500	420	1.4
Di-2-ethylhexyl Azelate	2.944	1132	6260	400	1.5
Di-heptyl Carbitol Adipate	4.128	5641	61130	440	0.15
Di-C ₉ Oxo Azelate	4.241	2907	Viscous	400	0.88
Di-2-ethylbutyl Carbitol Adipate	3.686	3522	40310	440	0.20
Di-C ₁₀ Oxo Adipate	3.598	2954	23000	450	0.85
Di-C ₁₀ Oxo Sebacate	4.702	4191	28860	465	0.31
Trimethylolpropane tri-n-octanoate	4.046	3276	22180	485	0.21

3. Glycol Diesters

Diesters in which the center portions are derived from glycols are of interest in this work as a means of increasing the availability of synthetic esters. A few of the glycol diesters are very much like dibasic acid diesters in properties. However, most of them are poorer. In general, the viscosity-volatility properties of polypropylene glycol diesters are good when straight chain acids are used, and poor when branched chain acids are used. The better polypropylene glycol diesters appear to be superior to the best polymethylene glycol (alkane diol) diesters for which data are available. As shown below, tripropylene glycol dicaproate is superior in all respects to pentanediol-1,5 di-2-ethylhexanoate, both esters having about the same viscosity at 210°F. Very little additional data have been obtained on the polymethylene glycol diesters, but they do not appear particularly promising. Diesters made from polyethylene glycols and branched chain acids have poor viscosity-volatility properties. These diesters are better, however, than the corresponding polypropylene glycol diesters utilizing branched acids. For example, the di-2-ethylhexanoate of diethylene

glycol has a lower vapor pressure and lower viscosities than the same acid ester of dipropylene glycol. When straight chain acids are employed with polyethylene glycols, the esters are likely to have high melting points.

Viscosity-Volatility Properties of Glycol Diesters

	Viscosity, Cs. @ °F.			Pour or (Melting) Pt., °F.	Flash Pt., °F.	Vapor Pressure, mm. @ 400°F.
	210	-40	-65			
Tripropylene Glycol dicaproate	2.134	591	3572	<-75 (WNC)	395	6.3
Pentanediol-1,5 di-2- ethylhexanoate	2.115	958	5452	<-75 (WNC)	390	8.6
Di-sec.-amyl sebacate	2.271	528	2970	<-75 (WNC)	375	6.4
Diethylene glycol di- 2-ethylhexanoate	1.969	1152	8579	<-75 (WNC)	360	8
Dipropylene glycol di-2-ethylhexanoate	2.204	2522	Viscous	<-75 (WNC)	355	12
Diethylene glycol dipelargonate	2.897	Solid	Solid	0 (+11)	405	--
Tetraethylene glycol dicaproate	2.552	1055	Solid	-60 (+1)	415	1.7

WNC: Would not crystallize after 15 hours at -94°F.

The volatilities and viscosity levels of glycol diesters can be varied over a fairly wide range by judiciously choosing the monobasic acids and polyalkylene glycol necessary to give desired properties. It was shown earlier that with tripropylene glycol, the upper molecular weight limit (because of partial crystallization at -65°F.) is reached with pelargonic acid (C₉). In view of the excellent properties shown for di- and tri-propylene glycol diesters and the apparent tendency for multi-ether linkages in glycol diesters to give lower melting points, it is felt that tetra-propylene glycol and higher polypropylene glycol diesters (with straight chain acids) would also give esters having satisfactory viscosity-volatility properties. These materials would be comparable to the more viscous di-basic acid diesters, such as di-C₁₀ Oxo or di-C₁₃ Oxo adipates. However, no data are available to demonstrate this. With polyethylene glycols, which are more readily available than polypropylene glycols, the choice of suitable acids appears to be even more restricted. As stated previously, this has been found true in the case of several polyethylene glycol diesters where high melting points were observed. As is shown below and in Appendix Table 44, optimum viscosity-volatility and pour point properties can be

obtained in polyethylene glycol diesters by employing one branched and one straight chain acid to give a mixed ester. The chief advantage over the non-branched structure is in pour point, whereas two mols of branched acid gives an ester of higher viscosity at low temperatures.

Viscosity-Volatility of Glycol Diesters

	Viscosity, Cs. @ °F.			Pour or (M.P.), °F.	Flash Pt., °F.	Vapor Pressure, mm. @ 400°F.
	210	-40	-65			
Polyethylene Glycol 200 dicaproate	2.920	1532	--	-65 (-27)	420	2.9
Polyethylene Glycol 200 mono-caproate mono-2- ethylbutyrate	2.918	1851	18860	<-75 (WNC)	420	3.5
Polyethylene Glycol di-2-ethylhexanoate	2.810	2977	30985	<-75 (WNC)	400	1.3

4. Dense Center Polyesters

The introduction of some branching into such esters as pentaerythritol tetra-caproate to reduce the melting point has an adverse effect on the viscosity-volatility properties. The vapor pressure increases and, as discussed previously, the low temperature viscosity is higher as a result of the expected poorer viscosity-temperature relationship. This effect is illustrated in the following table. Data on di-C₁₀ Oxo sebacate are shown for reference.

Dense Center Polyesters - Viscosity-Volatility Properties

	Viscosity, Cs. @ °F.		Melting Pt., °F.	Flash Pt., °F.	Vapor Pressure, mm. @ 400°F.
	210	-40			
Pentaerythritol tetra-caproate	4.133	4656	+21	470	0.25
Pentaerythritol dicaproate di-2-ethylbutyrate	4.660	16400	WNC	470	0.60
Di-C ₁₀ Oxo sebacate	4.702	4191	-76	465	0.31

C. Evaporation Rate of Synthetic Lubricants

The development of a test to measure lubricant volatility under more realistic conditions than are employed in flash point or vapor pressure determinations was recently undertaken in this work. It was felt that flash point was too easily influenced by volatile contaminants which might actually constitute only a very small proportion of the lubricant material. On the other hand, the closely controlled conditions and rather complex apparatus used in determining vapor pressure can hardly be likened to actual equipment in which synthetic lubricants are used, and where conditions may be conducive to evaporation losses. Consequently, to learn more about the property of volatility, a high temperature evaporation test has been employed. In this test a 30 gram sample of the test oil is heated in a glass tube (35 mm. i.d.), immersed in an oil bath at 392°F. for 5 hours. Nitrogen, at a rate of 2 liters per minute, is passed over the surface from a 10 mm. orifice located about 2 inches above and directed at the surface of the lubricant. The gas exit arm of the 11 inch tube is located 4 inches above the surface of the bath. Hourly weighings are made to determine the weight of the sample evaporated. Analysis of the test results of a number of lubricant materials evaluated showed that the rate of evaporation for pure esters remains virtually constant, as expected, for the duration of the test. This is shown in Appendix Figure 14 by the linear relationship obtained when per cent evaporation is plotted against time. The evaporation rates of a Grade 1010 mineral oil and a polyglycol lubricant were not linear, reflecting the fact that these compositions are mixtures of compounds of varying volatilities. The correlation between flash point and evaporation in this test was rather poor. However, the evaporation after 1 hour was found to be related fairly reliably to the vapor pressure at 400°F. These results are tabulated below and shown graphically in Appendix Figure 15.

Evaporation of Synthetic Lubricants

	<u>Wt. % Evaporated, 1 Hour @ 392°F.</u>	<u>Vapor Pressure mm. @ 400°F.</u>	<u>Flash Pt., °F.</u>
Di-2-ethylhexyl sebacate	0.7	0.78	430
Di-C ₈ Oxo adipate	1.7	2.6	385
Di-butyl phthalate	10.0	14.0	340
C ₈ Oxo decanoate	12.7	27.0	330
MIL-O-6081, Grade 1010 Mineral Oil	14.8	--	290
UCON LB-70X	18.3	65	280
2-Ethylhexyl 2-ethylhexanoate	22.3	120	270

These results indicate that the evaporation test gives about the same information on volatility as that obtained in vapor pressure determinations. The evaporation test has the advantage of simplicity, however. Several obvious modifications can be made to this test to simulate still more realistic conditions. Exposure of the test oil to air and agitation as well as high temperatures would be more like service conditions, but a combined oxidation stability-evaporation test of that type would probably be a less useful tool in exploratory work.

D. Oxidation Stability Studies

One of the most important properties of a synthetic lubricant designed for high temperature operation is its stability in the presence of oxygen and its corrosiveness to metals normally used in the equipment being lubricated. A limited amount of work has been undertaken to determine the oxidation stabilities of synthetic esters and what factors cause variations in their stabilities. A modification of the MIL-L-6387 Oxidation-Corrosion Stability Test was used in this work. It consists of bubbling air at a rate of 5 liters per hour through a 100 gram sample in the presence of strips of copper, aluminum, magnesium, and steel at a temperature of 347°F. (175°C.). The test is continued until a sharp increase is obtained in the neutralization number, which is determined every 24 hours by removing a 10 gram sample. The stable life of the ester is indicated by the point at which this relatively rapid increase in acidity occurs. The gain or loss in weight of the metal strips is recorded, but in these tests little significance is given to these data, since corrosion may become unrealistically severe when the oil has been oxidized to a high neutralization number. The stable life of an uninhibited ester is very short. Consequently, an 0.3 wt. % concentration of phenothiazine has been used as the oxidation inhibitor. This concentration will not prolong the test to an inconvenient length of time, as would be the case for many esters if higher concentrations were used.

It was pointed out in Appendix III of this report that impurities are considered to be the chief antagonist in causing variations in ester stability. For example, a distilled grade of di-2-ethylhexyl sebacate (Plexol 201W) appeared to be more stable than the less pure plasticizer grade (Plexol 201). The stability of a batch of plasticizer grade di-C₈ Oxo adipate (Plexol 244) could not, however, be improved by stripping, distilling, or charcoal treating. In the current study a number of other esters have been partially purified mainly by stripping off the first 5% and then evaluating the undistilled 5-100% portion. Information on any effects of low boiling impurities and the relative stabilities of esters could thus be obtained. These esters were run in duplicate to give an indication of the reproducibility of the test. As shown in the summary

table below and in Appendix Table 49, stripping gave no definite improvement in stability. In all cases the difference between the untreated and the stripped esters appears to be within the reproducibility of the test, which is not as good as desired. It will be noted that wide variations in stabilities can be obtained depending on the ester selected. Certain esters have substantially higher stable lives than others even though they may be only different batches of the same material. Di-2-ethylhexyl adipate has a surprisingly good stable life of about 150 hours whereas di-C₈ Oxo adipate is stable in this test for about 85 hours (Batch II), 45 hours (Batch I), and 25 hours (PX-208). Certain glycol diesters are at least equivalent to the better dibasic acid diesters. Esters derived from secondary alcohols possess oxidation stabilities equivalent to primary alcohol esters in this test. However, at higher temperatures (above about 400°F.), the secondary alcohol esters would be expected to be poorer based on thermal stability studies at these temperatures, although no substantiating data have been obtained in this program.

Oxidation Stability at 347°F.

Ester + 0.3% Phenothiazine	Stable Life, Hours	
	Untreated, 0-100%	5% Stripped Off, 5-100%
Di-2-ethylhexyl adipate (Flexol A-26)	140, 160	115, 140
Di-C ₈ Oxo adipate, Batch II (Plexol 244)	85, 85	75
Di-C ₈ Oxo adipate, Batch I (Plexol 244)	45, 45	40, 40
Di-C ₈ Oxo adipate (PX-208)	30, 20	35, 20
Dipropylene glycol di-n-octanoate	95	--
Triethylene glycol di-2-ethylhexanoate (3G0)	70, 55	70, 60
Di-sec. amyl sebacate	90	80, 75

E. Thermal Stability Studies

Besides good oxidation stability, it is also desirable for a synthetic lubricant to have good thermal stability. This is a property which is inherent in the molecule and probably cannot be improved by physical means, such as by the use of inhibitors or additives. The reaction involved when a synthetic diester is thermally decomposed is generally considered to be one giving olefins, half esters, and the original dibasic acid. Although other products, such as water, carbon dioxide, aldehydes, alcohols, etc., have been reported, olefins and acids appear to be the chief products of this reaction. The thermal stabilities of a number of esters studied under the terms of this contract have been determined by heating a 20 to 50 ml. sample of the ester at 392°F. for 48 hours in a closed tube under a small positive nitrogen pressure. In a few cases the test has been run at 455°F. The change in neutralization number occurring during the test is believed to be indicative of the decomposition that has occurred, and is converted to per cent decomposition assuming that the original dibasic acid is the only acidic decomposition product. As was shown in the fifth quarterly report,*purity of an ester may have a marked effect on the thermal stability of the ester. To obtain further information along this line several esters were stripped to remove any light-end impurities. The undistilled 5-100% portion was then subjected to the thermal test and compared with the original material. As shown by the following data taken from Table 51, any improvement obtained by employing this stripping procedure appeared to be generally small and insignificant in all cases except those of C₈ Oxo adipate (PX-208) and C₈ Oxo sebacate (PX-408). A small amount of water (dissolved or from unreacted alcohols) was present in these materials and was removed during the stripping operation. This water may have been responsible for the poorer stabilities of the original diesters. The presence of water would tend to promote hydrolysis and consequently increase the acidity.

*See Appendix III.

(Data on following page)

Thermal Stability - Effect of Refinement
392°F.

<u>Compound</u>	<u>Neut. No. Increase mg. KOH/gm.</u>	<u>Decomposition % of Theoretical</u>
Di-2-ethylhexyl adipate	0.14	0.05
Same stripped, 5-100%	0.04	0.01
Dicapryl adipate	42.0	13.9
Same stripped, 5-100%	40.9	13.5
Di-C ₈ Oxo adipate, Batch I	0.24	0.08
Same stripped, 5-100%	0.20	0.07
Di-C ₈ Oxo adipate (PX-208)	5.43	1.79
Same stripped, 5-100%	1.35	0.44
Di-C ₈ Oxo sebacate (PX-408)	5.86	2.22
Same stripped, 7-100%	1.02	0.39

The initial ester acidity does not appear to have any appreciable effect on thermal stability although it is conceivable that certain acidic materials could catalyze the thermal decomposition of an ester. A high acidity sample of di-C₁₀ Oxo adipate (initial Neut. No. of 8.08) gave essentially the same thermal stability before purification as it did after the acidic materials were removed (Neut. No. of 0.07). No significant differences appear in the stability at 392°F. of adipates and sebacates produced from primary alcohols. However, with secondary alcohol esters, which are generally less stable thermally than the primary alcohol esters, the sebacates appear more stable than the corresponding adipates. For example, capryl sebacate decomposed only 1% compared with 14% for capryl adipate. The sebacates of secondary amyl and hexyl alcohols are likewise reasonably stable at 392°F. At higher temperatures, however, as shown by the Petroleum Research Laboratories of the Pennsylvania State College, secondary alcohol sebacates decompose about 70% in 20 hours (500°F.) compared with 1 to 2% for primary alcohol sebacates, azelates and adipates. This thermal instability of secondary alcohol esters can be conveniently circumvented by converting the secondary alcohol to a primary one through the use of ethylene oxide. The improvement in thermal stability obtained by employing this technique is outstanding, as shown below with data obtained at 392° and 455°F. on dicapryl adipate and dicaproxyethoxyethyl adipate. It will be noted also that several similar Carbitol type adipates made from secondary alcohols are equivalent in thermal stability at these temperatures to one

made from a primary alcohol (2-ethylbutanol) and two ethylene oxide units. Complete data on thermal stability of esters at 392°F. are given in Appendix Table 51, and at 455°F. in Appendix Table 53.

Thermal Stability of Secondary Alcohol Derivatives
392° and 455°F.

Material	Neut. No. Increase, mg. KOH/gm. @°F.		Decomposition, % of Theoretical @°F.	
	392	455	392	455
Dicapryl adipate	42.0	*	13.9	100
Dicaproyethoxyethyl adipate	1.79	2.90	0.91	1.47
Isopropoxyethoxyethyl adipate	0.33	0.84	0.12	0.31
Diheptoxyethoxyethyl adipate	0.40	1.59	0.19	0.71
Di-2-ethylbutoxyethoxyethyl adipate	0.37	0.68	0.16	0.29

* No liquid sample remained at end of test. White crystals (adipic acid) had sublimed to cool portion of tube.

Propylene oxide can probably be used interchangeably with ethylene oxide in this conversion of secondary alcohols to more stable alcohols, but such esters have not been investigated in thermal stability tests. It is known, however, as discussed in the fifth quarterly report,*that diesters of polypropylene glycols (which are secondary glycols) possess thermal stabilities at 392°F. equivalent to similar diesters made from polyethylene glycols (which are primary glycols and therefore would be expected to give more stable diesters). As shown below with data taken from Appendix Tables 51 and 53, dipropylene glycol di-n-octanoate is essentially equivalent to polyethylene glycol diesters in thermal stability even at 455°F. The thermal stability of tripropylene glycol di-n-octanoate at 455°F. is not as good. The data indicate that this glycol diester would probably be unsatisfactory at a somewhat higher temperature, since at 455°F. it shows 2.34% decomposition.

*See Appendix III.

(Data on following page)

Thermal Stability of Glycol Diesters
392 and 455°F.

Material	Neut. No. Increase, mg. KOH/gm. @ °F.		Decomposition, % of Theoretical @ °F.	
	392	455	392	455
Dipropylene glycol di-n-octanoate	0.34	1.52	0.12	0.52
Tripropylene glycol di-n-octanoate	-0.10	5.79	0.0	2.34
Polyethylene glycol 200 dicaproate	0.41	0.49	0.14	0.17
Polyethylene glycol di-2-ethyl- hexanoate (4G0)	0.0	0.59	0.0	0.23
Di-C ₁₀ Oxo Sebacate	0.20	2.36	0.09	1.01

Data also presented in Appendix Table 51 show that esters produced from pentaerythritol and trimethylolpropane and straight chain acids possess excellent thermal stabilities at 392°F., and that the introduction of some branchiness does not impair this property. Tri-n-butyl aconitate, which has a point of unsaturation and a structure which might be expected to undergo decarboxylation, is nevertheless fairly stable at 455°F. (Table 53), giving only 3.6% decomposition. This triester, however, does not appear to be a very promising lubricating oil component because of its poor oxidation stability at 347°F. (Table 49).

F. Lubrication Studies

This important phase of work is now being studied intensively under this contract, as described generally in Section H - Future Work. A considerable amount of information has been obtained in the 4-Ball E.P. Machine and the S.A.E. Machine.

APPENDIX V

SEVENTH QUARTERLY
PROGRESS REPORT

I. DISCUSSION

This work on lubrication studies has been confined to the SAE load carrying machine and the 4-Ball E.P. test machine. The work with the SAE machine was directed toward developing a test which would adequately evaluate the load carrying properties of various lubricants for use in aviation turbo engines. The effects of various operating variables such as speed, shaft speed ratio, loading rate, and run-in were first investigated. Based on this work, a test technique was chosen for additional checking. Inasmuch as good results have been obtained to date, the operating conditions used for this work have been set up as the SAE-SOD Load Carrying Test.

In these studies, a number of synthetic oils (with and without load carrying agents) having viscosities in the range of 2.8 to 8 centistokes at 210°F. were used, in addition to two mineral oils. These mineral oils are as follows: Esso Turbo Oil 10 (MIL-L-6081, Grade 1010), which has relatively low load carrying properties; and Esso Aviation Oil 100 (MIL-L-6082, Grade 1100), which has adequate load carrying properties for high output turboprop and turbojet engines, but has unsatisfactory low temperature properties. These two mineral oils will be designated ETO-10 and EAO-100, respectively, in this discussion.

During the course of this work in the SAE machine, different batches of the Timken test cups were used. Initially, cups marked "B" and "C" were used. The supply of these cups ran out, however, and the rest of the work was done with a batch of test cups marked "U". The "B" and "C" test cups were essentially the same in hardness and surface finish, but the batch "U" cups were somewhat harder and had a slightly rougher surface finish. Lower failure loads were obtained with the batch "U" cups. As discussed later in the report, this difference in performance indicates the significance of small variations in the physical properties of the test cups. A similar problem is encountered in various gear rig testers; that is, variations between batches of gears affect the results obtained.

The 4-Ball E.P. Test results, discussed in a succeeding section of this Appendix, were obtained using the conventional procedure. The data reported from this test include only the load required to cause immediate ("no delay") seizure and the load required to cause welding. This is believed to be the most significant information obtained in this test.

A. SAE-SOD Load Carrying Test in SAE Machine

A test has been developed using the SAE E.P. Lubricant Testing Machine⁽¹⁾ for evaluating the load carrying ability of aviation gas

- - - - -

(1) The SAE Machine is described in the CRC Handbook.

turbine lubricating oils. This test is a modification of one of the tests used by the National Bureau of Standards. Comparison of these two tests and the more widely known CRC E.P. gear oil test is shown in the following table.

Tests in SAE E.P. Lubricant Testing Machine

	<u>SAE-SOD Test for Turbo Oils</u>	<u>Test Used By Nat. Bur. Stds.</u>	<u>CRC L-17 Test for Gear Oils</u>
Main Shaft Speed	1000 RPM	1030 RPM	1000 RPM
Shaft Speed Ratio	3.4:1	3.4:1	14.6:1
Test Cups	Timken T-48651	Timken T-48651	Timken T-48651
Run-in	50 to 200 lbs. for 2 minutes.	200 lbs. for 1 minute.	150 to 200 lbs. for 30 seconds.
Loading after Run-in	Manual stepwise, 50 lbs. at 10 second intervals.	Automatic contin- uous at 78 lbs. per second.	Automatic contin- uous at 75 to 85 lbs. per sec.
Failure Load*	Minimum load at which scuffing of the contact surfaces of the test cups occurs.		

* In SAE-SOD test, if failure occurs during load change of 50 lbs., the failure load is taken as the average of the "old" and "new" loads.

The main differences among these tests are in shaft speed ratio and loading rate after run-in. The National Bureau of Standards test uses a lower shaft speed ratio than the CRC test, 3.4 instead of 14.6. The SAE-SOD test uses this lower ratio and also a much lower loading rate than the other two tests. Manual load applications of 50 lbs. at 10 second intervals (300 lbs. per minute) are used instead of the automatic loading at 75 to 85 lbs. per second (4500 to 5100 lbs. per minute).

Results obtained with the SAE-SOD test have shown reasonably good reproducibility, good spread between lubricants of widely different engine performance, and good correlation with the I.A.E. Gear Machine test. In addition, the test is not only sensitive to the viscosity of the lubricant but also to chemical structure and to surface-active ingredients. The results obtained in the SAE machine during the development of this test and under SAE-SOD conditions are tabulated in Appendix Tables 54, 55, and 56.

1. Effect of Viscosity, Chemical Structure,
and Surface-Active Ingredients

The effect of differences in chemical structure and viscosity level on load carrying ability are apparent from Appendix Figure 16. Increased viscosity gives higher loads before failure. The type 1 esters, a distinct class of compounds, appear to have better inherent lubricating properties than the type 2 esters, a chemically different class of compounds, over the viscosity range investigated. However, this difference

is not necessarily reflected in finished lubricants based on the two types of esters. Lubricating properties can be markedly altered through the use of addition agents.

The effect of surface-active ingredients on failure load is shown in Appendix Figure 17. Tricresyl phosphate increased the failure load 165 and 125 lbs. when used in 5% and 3% concentrations respectively in synthetic oils of 3.0 and 3.4 cs. viscosity at 210°F. The use of 0.4% of a sulfurized inhibitor gave an increase of 125 lbs. in a 5.0 cs. synthetic oil.

2. Correlation with I.A.E. Gear Machine Test

The correlation of the SAE-SOD test failure load with that obtained in the I.A.E. Gear Machine test is excellent for two mineral oils and several synthetics, as presented in Appendix Figure 18. Both the I.A.E. and the SAE-SOD tests also show reasonably good correlations with high-speed gear tests, and with the available field performance in full scale reduction gear set-ups. This correlation with gear tests appears better than that obtained for other simple laboratory lubrication tests. This is probably due to the ability of the SAE machine to recognize some of the same factors which affect gear lubrication.

3. Variation in Results with Different Test Cup Batches

The variation in results using different test cup batches and run-in loads is shown in Appendix Figure 19. Reducing the run-in load from 200 lbs. to 50 lbs. (with batch "B" and "C" test cups) apparently has little effect on failure load, giving essentially a numerical match correlation. There appears to be an advantage with the lower run-in load, in that more reproducible evaluations can be made on lubricants of lower load carrying ability, say in the range of 200 to 400 lbs. To illustrate, with 200 lb. run-in, Esso Turbo Oil 10 (Grade 1010 mineral oil) failed two times during the 200 lb. run-in and ran in a third test to 350 lbs. before failure. When using 50 lb. run-in, in four tests all failures occurred between 300 and 350 lbs. Results obtained at 50 lb. run-in load with batch "U" test cups averaged 130 lbs. lower failure loads than obtained with batches "B" and "C" test cups. The apparent explanation for this difference in performance is differences in the surface finish and hardness of the test cups as shown in the following table.

Physical Properties of Timken Test Cups No. T-48651

Test Cup Batches	Average Hardness Rockwell C-Scale	Surface Finish RMS Microinches	
		Range	Average
"B" and "C"	61.5	16-19	17.5
"U"	62.2	17-22	19.2

It appears that the "U" cups, which are somewhat harder and not quite as smooth, are slightly more resistant to polishing during run-in. Hence, the mating surfaces of the test cups may not be as smooth at the start of the loading period as when using the "B" and "C" test cups. An attempt, however, to obtain a higher failure load with the "U" cups by extending the run-in period to obtain better polishing before loading was unsuccessful. This test involved synthetic lubricant B-15 and "U" test cups, which were run-in in the following manner: 2 minutes at 50 lbs., 2 minutes at 100 lbs., 2 minutes at 150 lbs., and finally 2 minutes at 200 lbs. The equipment was then cleaned and cooled to room temperature without removing the test cups from their shafts. A new charge of lubricant B-15 was charged and the test restarted using the standard SAE-SOD test procedure of a 2 minute run-in (50 lbs.) followed by 50 lbs. loading each 10 seconds. Failure occurred during the load increase from 500 to 550 lbs. (525 lb. failure load). Thus, with the additional run-in, the failure load fell short of the 550 to 700 lbs. range obtained in the usual manner with the "U" cups and is far below the 700 to 775 lb. range obtained with the "B" and "C" test cups on this lubricant. Accordingly, it appears necessary to establish a correlation for each batch of test cups. This procedure has been found useful in the I.A.E. Gear Lubricant Test and is probably advisable in all load carrying tests unless very close limits are set-up on the surface finish, composition, and hardness of the metal test parts.

B. Effect of Operating Variables on Failure Load in SAE Machine

During the development of the SAE-SOD test procedure, a number of operating variables were investigated to determine their effect on failure load. A good part of this work was done at 3.9:1 shaft speed ratio(1).

1. Shaft Speed

Increasing the shaft speed lowered the failure load very significantly as shown in Appendix Figure 20. Roughly doubling the speed from 530 to 1000 RPM reduced the failure load by more than one-half for all four lubricants tested. In these tests, 200 lb. run-in was used followed by 78 lbs. per second loading. At the higher speeds, the relative distance the surface of one cup slides and rolls across the surface of the other is greater and the rate of heat generation is higher. Each of these factors tend to make the test more severe. At the higher speeds,

- - - - -
- (1) It was planned to conduct this work at 3.4:1 shaft speed ratio. However, some gears in the SAE machine were inadvertently interchanged resulting in the higher shaft speed ratio of 3.9:1.

the increase in heat generation means that at any given time (which corresponds to a given load) the temperature of the lubricant is higher. Likewise, at any given time the linear distance for which the cups have been in contact is also greater.

2. Loading Rate

Loading at a faster rate results in failure at a higher load. This is shown in Appendix Figure 21, where loading in a stepwise fashion at an average rate of 100 and 200 lbs. per minute is compared with loading at 4680 lbs. per minute (78 lbs. per second). This same effect is apparent in Appendix Figures 22 & 23 covering the range of 25 to 400 lbs. per minute average loading rate for mineral oil EA0-100 and synthetic oil B-15, respectively.

Loading at a slower rate, means that the sliding distance involved is greater before reaching a given load. This is in the direction of higher severity, causing lower failure loads. Looking at it another way, at loads above the maximum load which can be carried continuously by the oil without failure there is undoubtedly a definite lag time required before oil film rupture and scuffing occur. Therefore, the faster the loading rate, the more the load can be increased above the "maximum continuous" load during this "lag time" before failure occurs.

3. Effect of Run-in

Increasing the run-in load and time of run-in both tend to lower the failure load when using 78 lbs. per second loading rate. Test data on four oils are shown in Appendix Figures 24 & 25. As with speed and loading rate, there is a tendency for failure to occur at lower loads when the test cup surfaces are exposed for a longer time to the same load, or for the same length of time to a higher load.

It appears advisable to have at least a minimum run-in period of 1 to 2 minutes.

4. Effect of Shaft Speed Ratio

Increasing the shaft speed ratio tends to lower the failure load. The limited data available (on Esso Aviation Oil 100) is presented in the following table.

(Data on following page)

Effect of Shaft Speed Ratio on Failure Load

Lubricant: EAO-100, Grade 1100 Mineral Oil
Speed: 1000 RPM
Test Cups: Timken No. T-48651 Batches "B" and "C"
Temperature: Room Temp. (75-80°F.) at Start

Shaft Speed Ratio	Relative Sliding Between Cups Feet per Min.	Run-in Period	Loading After Run-in	Failure Load, Lbs.
3.4	346	50 lbs. for 2 min.	50 lbs. each 10 sec.	988
3.4	346	200 " " 2 "	50 " " 10 "	975
3.9	365	200 " " 2 "	100 " " 30 "	700
3.9	365	200 " " 2 "	100 " " 60 "	600
14.6	457	50 " " 2 "	50 " " 10 "	200

As shown in the table, at higher shaft speed ratios the sliding distance is greater per unit of time. This means that the same factors are involved as with an increase in speed. Namely, the generation of heat by friction is more rapid and at any given load the sliding distance has been greater. Both these make the operation more severe and bring about failure at a lower load.

C. Lubrication Studies in 4-Ball E.P. Tester

1. Effect of Viscosity

Tests were run in the 4-Ball E.P. Tester to determine the effect of viscosity upon failure load for relatively low viscosity mineral and synthetic oils. The results, shown in Appendix Table 57, indicate essentially no effect of viscosity. Three groups of oils were tried as follows: (1) refined mineral oils from 1.2 to 14.1 cs. at 210°F., (2) Oxo alcohol esters from 1.34 to 5.61 cs. at 210°F., and (3) blends of di-2-ethylhexyl sebacate (Plexol 201) and Acryloid HF-825 from 3.36 to 10.10 cs. at 210°F. Within each group, both seizure and weld loads were within experimental error showing that this 4-Ball E.P. test is not sensitive to variations in viscosity.

2. Effect of Chemical Structure

Although the 4-Ball E.P. Tester is not affected by viscosity, the seizure and weld loads are influenced by chemical structure and surface-active load carrying agents in the low viscosity synthetic oils. The tests which were conducted are shown in Appendix Table 58. The materials containing ether-oxygen linkages exhibited no better load carrying ability in

this test than the sebacates, adipate, and the succinate which were tested. The literature, however, indicates that some improved performance with this type of material is possible for steel-on-bronze lubrication.

The better performance of Complex Ester A over that obtained with the other esters shows that the 4-Ball E.P. test can recognize changes in chemical structure. The esters of Evanacid 3CS also give better performance in this test showing the effect of the sulfur-containing molecule. Tests on blends of the tri-n-hexyl ester of Evanacid 3CS with Plexol 244 (C₈ Oxo adipate) show nearly linear correlation of both seizure and weld loads with the concentration of the sulfur-containing ester. As discussed in previous reports, the esters of Evanacid 3CS, although effective load-carrying agents, are not believed to be satisfactory for turbo engine lubrication because of corrosion difficulties encountered at high temperatures.
